Abstract

Purpose – In response to the increasing number of open-source software (OSS) project initiatives and the increasing demand of OSS products as alternative solutions by industries, it is important for particular stakeholders such as the project host/supporter project-leading teams, and prospective customers to determine whether a project initiative is likely to be sustainable and is worth supporting. This paper aims to propose a concept of "health" indicators and an evaluation process that can help to get a status overview of OSS projects in a timely fashion and predict project survivability based on the project data available on web repositories.

Design/methodology/approach – For initial empirical evaluation of the concept, the indicators are applied to well-known web-based OSS projects (Apache Tomcat and Apache HTTP Server) and the results are compared with challenged projects (Apache Xindice and Apache Slide). The results are discussed with OSS experts to investigate the external validity of the indicators.

Findings – From a software project management point of view, a typical web-based OSS project can be viewed as a web-engineering process, since most OSS projects exploit the benefits of a web platform and enable the project community to collaborate using web-based project tools and repositories such as mailing lists, bug trackers, and versioning systems (CVS/SVN) to deliver web systems and applications. These repositories can provide rich collections of process data, and artifacts which can be analyzed to better understand the project status.

Originality/value – The paper provides information of value about open-source solutions.

Keywords Computer software, Project management, Internet

Paper type Research paper

This paper is part of larger research called Monitoring Distributed Software System Development and Operation. The objective is to define a more effective and efficient methodology for monitoring a distributed running system and distributed software project management in order to satisfy various stakeholder needs. This project has been partly supported by The Technology-Grant-South-East-Asia No. 124-2/BAMO/2005 and The North South Dialogue Scholarship Program EZA-Project 894/05, financed by ASIA-Uninet in cooperation with the Austrian Council for Research and Technology Development.

1. Introduction

Open-source software (OSS) has caught our attention by the success and quality of its projects on the market, despite the fact, that its development does not follow traditional software development principles. In certain software product classes, OSS offers comparable or better contributions than "closed source" commercial software products, making OSS a considerable alternative in many domains reaching from operating systems over web-frameworks and databases to office applications. However, many OSS projects are still in their initial phase, in an immature state or have reached the end of their life cycle, which means their survival seems heavily uncertain.

Our study begins with the question on how to improve the chances that an OSS project can stay "healthy" and to predict the chances for survivability for the next time periods (months or one quarter years ahead) or to reach success. Nowadays, a great number of OSS projects exists but for the individual it is hard to judge, whether it is worthwhile to take the effort of a closer look as a project.

In OSS, the project survival is a result of many underlying (connected) processes and cannot be easily determined. Just to give an example: developers are typically not paid for their work, but contribute voluntarily on their own motivation basis. Hence, the dynamic of the development process is much more difficult to estimate compared to that of a typical commercial project. This issue is problematic for certain stakeholders in OSS community to fulfill their goals such as prospective customers of OSS products in order to decide which products will provide long-term warranty and enhancements; the hosting project (e.g. Apache and Eclipse) to provide or to continue support for some projects under their umbrella; project leading teams who steer the project's direction based on project status in timely fashion. For this reason, the Apache Software Foundation (ASF) has to decide whether or not to accept new project initiatives and set them up the Apache Incubator.

The scale of the problem is escalating when a large number of projects should be monitored in parallel. The resulting OSS project monitoring faces ever-increasing demands to provide pertinent data from the dynamics of the projects, to help stakeholders cope with complex masses of data/information, to provide competitive discriminators based on the stakeholder values; and to provide the "health" status of the project.

We address these needs by proposing a concept and evaluation of "health indicators" in open-source projects. The basic argument for the strategy of our approach is derived from the analysis of literature and published studies. We apply the indicators to well known OSS web-engineering projects for initial empirical evaluation of the concept. We perform project data analysis on the data retrieved from several successful OSS projects and the challenged ones. We discuss the results with OSS experts to investigate the external validity of the indicators.

2. Related work

This section briefly introduces recent practices and related works that support the implementation of health monitoring in OSS web-engineering projects.

2.1 Open source software project as a form of web engineering

Web engineering represents a new discipline in software development, as its major concern is to develop web using the emerging internet technology. Based on the

definition of web engineering by Ginige *et al.* (2001), an open source web-engineering project (such as Apache Tomcat, Apache HTTP Server, Phyton, and Mozilla) can be seen as an extreme form of web engineering practices, as it heavily relies on exploiting the web platform and web-based tools during its development process. Current trend shows an increasing number of OSS products adoptions in the web engineering community. Just to give an example, Netcraft (http://news.netcraft.com/archives/web server survey.html, accessed February 20, 2007) Web Server Survey discloses that more than 70 percent of the web sites on the internet are using Apache HTTP Server.

Furthermore, our observations on 178,951 projects listed in Sourceforge (http://sourceforge.net/, accessed February 18, 2007) reveals that the top five project categories are internet application (15.4 percent), Software development (15.1 percent), System (12.4 percent), Communication (10 percent), and Game/Entertainment (9.3 percent). Sourceforge ranks these projects into several categories: Planning (18,156 projects), Pre-α (15,314 projects), α (17,190 projects), β (23,198 projects), Production/Stable (19,531 projects), Mature (1,675 projects), and inactive (2,124 projects). Although there is no formal definition from Sourceforge for these categories, these facts depict that most of the projects are web-related applications which are still in their early stages or already at the end of their lifecycle, and only a small portion (less than 2 percent) of the projects have reached maturity means they already have several stable releases.

Capiluppi *et al.* (2003) suggest that typical OSS development seizes several problems such as the lack of requirement elicitation, no *ad hoc* development process, less attention to quality and documentation, and poor practices of project management. Another typical characteristic is the high level of distribution, as OSS is built by a potentially large number of volunteers who are geographically distributed. It is worth noting, however, that currently a number of important OSS projects are supported by companies and some participants are not volunteers (e.g. JBoss, Apache JackRabbit, or OpenOffice). Although the development process in OSS project seems less organized, a recent study (Valverde *et al.*, 2006) suggested that the social structure in OSS projects could provide some hierarchy or meritocracy (such as in Apache) of management and controlling based on self-organizing patterns. This makes OSS projects interesting objects for the empirical study of web/software project management.

2.2 Software project monitoring

To obtain the actual status of the project, software project monitoring is required to supply timely, accurate and comprehensive project information as the basis for analysis and decision making. During the development, the monitoring process should balance the observation from both:

(1) time relevant process events data; and

(2) product-relevant artifacts data as they complement each other.

This combination will provide more accurate and less-biased project information. In general, there are two monitoring approaches: tool-based and human-based monitoring. The tool-based approach seems most suitable for monitoring frequently a large number of process events data, or when human resources for monitoring are hard to obtain. On the other hand, the human-based approach seems favorable for a weekly/monthly process such as personal reporting as the summary of activities and

progress status, and go to more detail if necessary by directly interviewing the team member.

Traditional software project management (Phillips, 2004; Royce, 2000) focuses on tracking formal achievements such as the progress and financial obligation and analyzing the merit of project participants based on routine personal reports and deliverables. As the consequence, most of the traditional project management is human-based monitoring, which often misses the process and information during its project execution. This can be very risky; if a problem occurs, as Keil *et al.* (2004) found, participants tend not to report the actual condition of the project. Hence, additional data for comprehensive balanced reporting are needed before and during a crisis for raising issues well in advance to identify and to mitigate project risks.

Current trends in distributed software development such as open source web-engineering project and web information system have led to new challenges regarding the scalability and expressiveness of methods (Schewe and Thalheim, 2005), especially when the project has to face:

- a large amount of process data to be monitored;
- shortage of human resources for monitoring; and
- most importantly, the loosely coupled project community as the result of a global project work.

Consequently, monitoring such a system using only a human-based approach is likely to be costly, time consuming, and error prone.

In this situation, a project leader should rely not only on human-based reports and project artifacts, but also supplement these sources of information with tool-supported process event data monitoring. Tool-driven health monitoring system has been successfully adopted by industries, reaching from hybrid system to business activity process monitoring (Thai *et al.*, 2001), which in principle can be adopted in software project management domain. Other study (Schatten *et al.*, 2001) suggested a web-based OSS tools for project monitoring, particularly for dislocated or distributed development such as OSS projects.

OSS projects consist of large sets of process data residing in some projects' repositories. To extract useful information from such data repositories, we need web data mining, starting with data preparation which may involve data cleaning, data transformations, selecting subsets of records and in case of data sets with large numbers of variables – performing some preliminary feature selection operations to bring the number of variables to some manageable range.

Several studies have used process data of the existing open-source projects to better understand the aspects of successful distributed development. These studies observed the OSS projects by manually or by tool supported mining project repositories such as mailing lists, bug database (Mockus *et al.*, 2002), SVN/CVS (German, 2004), and changes log (Chen *et al.*, 2004). The results clearly portrayed the development process pattern and the importance of community involvement in OSS projects. However, further works are required to better understand the OSS project, to distinguish different status of projects and to estimate the project survivability.

3. The concept of OSS health monitoring

Web engineering, in particular in an OSS project, is a process with a long life cycle. To ensure a project's survival, a decision maker needs to evaluate health status and recognize early symptoms of illness. Such indication could be obtained by correlating measures that are available during the development. Our research focused on shaping the "health" concept for OSS web-engineering project, later we proposed several health indicators, based on measurement of project performance metrics reside in OSS projects repositories.

3.1 The "Body" of open-source project

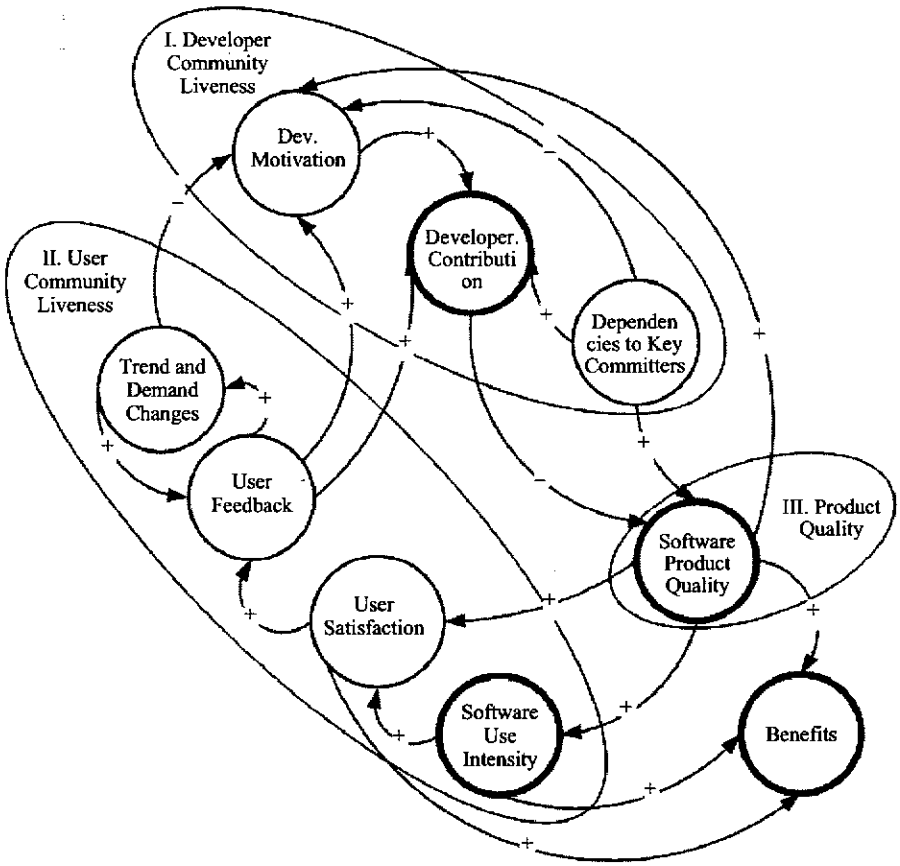
Crowston *et al.* (2003) suggested the success factors of an OSS project consisting of software creation/developer contribution, software use intensity and software quality. However, to better illustrate the impact of these factors and typical risks during the development process, in our context; we model the OSS project as a body consisting of three major components: the developer community, the user community and the software product. We picture in Figure 1 the success factors and risks as interrelated states and activities which indicate the project component status. We assume that the survivability of the project is the result of the state of well being (liveness) of both communities indicated by facilitating rapid creation and deployment of the incremental product releases or patches (www.catb.org/esr/halloween/, accessed February 20, 2007). Furthermore, this release should satisfy relevant user needs. The following subsection describes an analysis about our model in more detail, based on literature review and web observation.

3.1.1 Developer community liveness. Successful OSS projects are not one time event. It is a process of a long life cycle which was first coined by Eric Raymond as "scratching the developer itch." The developers' community continues to contribute, develop, enhance, maintain and release the products developer contribution, iteratively in a typical OSS project management style. Therefore, in order to survive a project should attract more developers and boost their motivation.

Studies on the projects hosted in Sourceforge by Krishnamurthy (2002) and Manenti *et al.* (2005) signify that the developer community may consist of one developer only (as a single fighter) up to more than 250 developers at one time. They also disclose that 86.2 percent of the projects employ less than six developers during the development processes.

A survey from The Boston Consulting Group (2002) disclosed that the developers' motivations to join an OSS project are to stimulate their intellectual, to enhance their skills or to have access to the source code and user needs. As most of the developers join the OSS project for their self-satisfaction, the degradation of developer motivation are not trivial and very likely to cause the project into deep problems if there is no appropriate counter measure. Lerner (Lerner and Triole, 2002) suggested that developers' loyalty can be obtained by giving some incentives such as opportunity to contribute, community attention and recognition based on merit to the project.

According to Gacek (Gacek and Arief, 2004), developer in OSS project is comprised of code/peripheral developers and core developers which also called as committers. A project can generally be well developed and provide regular releases, which are appreciated by the user community, but it might actually be driven by very few active committers (dependencies to key committers). In the worst case, the project might



Note: The status of an OSS project is the result of interrelated factors residing within the project communities and the product quality

Figure 1.
Causal model of an OSS project

depend on one particular person. This is obviously a risky situation for the project and its users as the key committers may leave which then brain drains the project, and demotivates other developers, as the case in Apache Slide (Wahyudin *et al.*, 2006).

The dominance of the key committers may also reduce the opportunities of peripheral developers to contribute, which can be considered as a hostile action. This dependency has been considered as a major issue by ASF that should be comprehended by all new project initiatives under the Apache-incubation process. Other typical risky situation that may threaten OSS project is the shift of market or the change of technology which causes project's disorientation and consequently demotivates the developers to abandon the project (like Native XML Database).

3.1.2 User community liveness. The second group in the OSS project community is the user who observes, downloads and then uses the software product for certain objectives (e.g. curiosity, work functions, and user needs). The level of software use intensity will be amplified when certain quality attributes of the software product

satisfy the user value expectation. Compared to those of commercial software products, the users in OSS project are expected to be more active to provide feedback on the functionalities of the product release. Some studies (Fogel, 2005; Raymond, 2003) reported that most of the bug reports and the feature requests came from the users community, which were then responded by the developer community by submitting patches or new features. Eventually, these practices caused rapid changes into the code and documentation. However, the user-expectations may change over the time due to the technology evolution, needs of reorientation or some other reason. Eventually, these changes imply the shift of trend and demand of the market which consequently impact the development process. Hence, it is fair to say that the user community has significant impact on the OSS project community liveness in the whole and on the quality of the software product released.

3.1.3 Product quality. The typical characteristics of OSS such as being open-code based and no formal project management have raised some debates about the quality of the released products. However, a survey from Boston Consulting Group (2002) suggested that open source community is mostly comprised of highly skilled IT professionals who have, on the average, over ten years of programming experience and it is not exaggerated to assume that these people are well knowledgeable to produce a good quality code which is contrary to popular belief about hackers.

Recent study in OSS quality (Aberdour, 2007) suggests several software engineering quality model that typically practiced in OSS project community such as peer review to assess whether a contribution merits from developer acceptance into the code base. The bazaar style of OSS development facilitates rapid releases which make the implementation of peer review. The existence of quick response to reviewers comments and code keeps the contributor involved and interested (Raymond, 2003). As in a large project such as Apache HTTP Server, peer review is practiced not only for assessing the quality of contributed code but also applied for a new idea/solutions submitted to the developer community which need to be discussed, and reviewed before being planned for development.

The second typical quality practices are people management in reporting, reviewing, debugging and resolving issues. Aberdour (2007) advocates on this practice to include establishing an effective environment and culture which is as important as system design. This means there should be a pre-defined coordination mechanism (Fielding, 1999), conflict management (such as voting) (O'Reilly, 1999), encouraging innovation and creativity (Lawrie and Gacek, 2002), and affectionate attention from the community (Lerner and Triole, 2002).

The third and the most prominent quality practice is bug tracking activity. In a traditional project, a bug tracking is similar to an inspection which is effective but also expensive quality assurance. A study from Ximian Evolution (German and Mockus, 2003) disclosed that after a product release, the user and larger part of the OSS community typically shift their roles in reporting, reviewing and resolving bugs/issues. These practices of software engineering quality model influence the community liveness by encouraging project participants to be involved and be motivated to keep contributing, resulting in a product that extends rapidly and reaches high quality. Here, we conclude that only a healthy community can produce high-quality software.

3.2 Project health indicators

In the previous section, many different parameters had been taken into consideration to get an impression of the status of a project which is actually not an easy task. This is particularly problematic, if a large number of projects need to be monitored. Based on the described success factors, there are some indicators that experts routinely use to assess an open-source project, such as:

- *Open issues, service delays.* Bugs and issues are listed in the bug-tracking system, but the fixes are not done in appropriate time.
- *Proportions.* We calculate the proportions of activity in the community, e.g. the volume of mailing list postings, bugs status changes per time slot, updates in the SVN; and use these metrics to compare different projects to try to learn what "healthy" relationships are.
- *Communication and use intensity.* If a project has a healthy community, there is indication of strong relationship between some measures such as the number of download compared to mailing list postings and the active developer interaction in (different) mailing lists.

In a distributed project, a set of certain software engineering tools and standards have been established to support open-source projects. The tools are used where activities of developers can be interpreted as process events (time stamped date points) data. Typical important tools are: source code repositories, systems documentation (source, user), bug tracking, mailing lists, software forum (web, newsgroup), and Wiki content management. These tools provide informative but scattered pools of data during a project's life-cycle. Obviously, developers use these tools and data for coordination, communication, and configuration management.

We propose an approach by unifying the data coming from different systems into a coherent format for analysis. We expect not only data for historical analysis but also for daily or weekly monitoring and analysis. If this is achieved, it is possible to monitor the status of the project's health regularly and receive early warning signals, if bad smells occur. For analysis, it is necessary to collect, filter, and correlate these data elements. While a human expert has to do the analysis by looking into the different systems, only little tool support is readily available for automatic and continuous "real time" analysis of project status.

In today's practices, health indicators and healthy community of OSS projects have increasingly become important issues. Just to give an example, the Apache Incubator (http://incubator.apache.org/, accessed February 1, 2007) defines that a new project initiative may pass the incubation process by fulfilling some requirements: the project must have a healthy community indicated by an active collaborative works within the community and it consists of diverse core developers. For the diversity of core developers measurement, we can quantify the number of independent core developers based on their background profile. The diversity is important because it:

- guarantees a sustainable development, as the project will be less dependent on a single developer; and
- brings variety of competencies to enrich the quality.

However, our interview with OSS expert suggests that this indicator is best to be obtained manually by retrieving each committer personal data and analyzing the project profile. Active collaborative works are indicated by several health indicators such as the coordination activities, conflict resolutions (number of voting), intensity of usage, bug service delays, and the proportion of the developer contribution to the project repositories. In this paper, we focused on the last two health indicators.

The service delay, in a commercial project, is the time interval to respond a service request from a customer and time to fulfill the service. While in OSS project, we define the service delay as a function of time to respond and time to resolve an issue/bug. The bug/issue service delay is important as most of the activities in OSS project are derived from bug or issue report; eventually, a project which has slow response and resolution time will face problems such as user dissatisfaction and bottleneck in the development process. The second health indicator is the proportion of the developer contribution. These indicators are very important to obtain an outlook of software creation performance and the current developers' motivation state. Both of the indicators are derived from the aggregation of metrics, which at the lowest level the metrics are obtained by mining the project repositories as shown in the Figure 2.

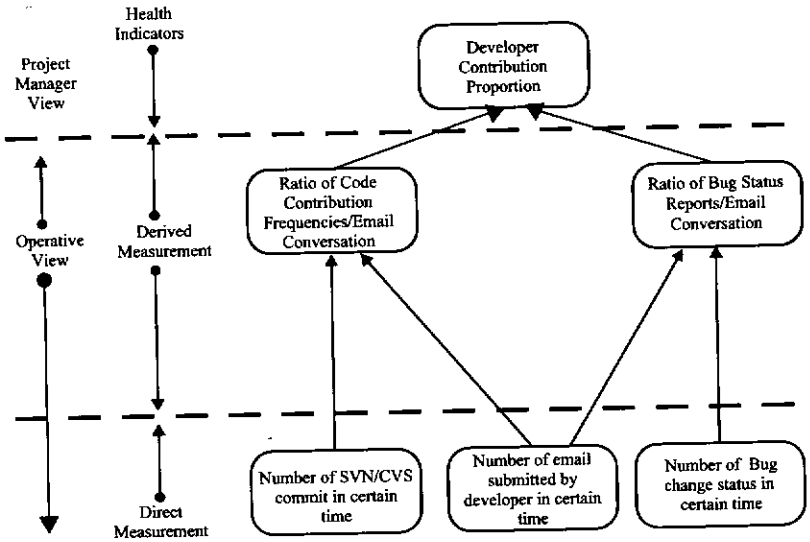
3.3 Stakeholder value proposition for OSS project health monitoring

The stakeholders in OSS project are represented by each individual in the community. To better understand their expectation about project monitoring, we need to elicit their values; starting by defining win conditions and their key measurement and then select which requirements meet the win conditions (Biffl *et al.*, 2005). In this paper, we focus on eliciting the value of project manager as the most prominent user in monitoring day-to-day a large (employing more than 20 active developers as listed in each project's web site) web-engineering project.

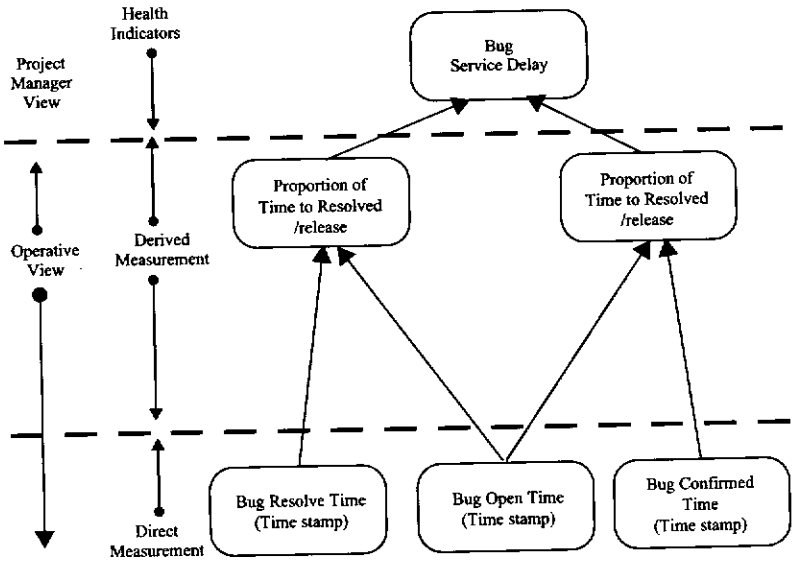
Based on our observation from several OSS projects, we found that a project is typically led by a group of key committers or steering board. Just to give an example, from projects under Apache Foundation umbrella, we found a form of project leading team called as Project Management Committee (PMC). The PMC members are originally elected from active committers based on their merits within a project and then appointed by the Foundation Board to sit in the PMC (later, we refer this individual member as the project manager).

According to the ASF (www.apache.org, accessed January 28, 2007), the main roles of the PMC are to ensure that all legal issues are addressed and the procedure is followed, the alleviation of any bottlenecks and conflicts, the overall technical success of the project and that each and every release is the product of the community as a whole. PMC is also responsible to give strategic decision, to further the long-term development and the health of the community as a whole, and to ensure that balanced and wide-scale peer review and collaboration do happen.

These roles depict the need to monitor the health of the community in timely fashion, and to quickly respond appropriately against certain status during project execution. Hence, the common win conditions of project manager in monitoring OSS project are:



(a) Developer Contribution Proportion



(b) Bug Service Delay

Note: The measurement selection for monitoring project status, depends on the stakeholder values. The Operative level measure direct (low level) metrics from project repositories which are then transformed into higher level metrics. Project manager analysis the health indicators as the results of correlation of these aggregated metrics

Figure 2.
Measuring OSS project health indicators

(1) *To retrieve comprehensive indicators which indicate the actual status of the project performance.* During execution, a project may produce a significant number of data, artifacts and project information which can be further processed as indicators. However, due limitation of observers in OSS project as they are not a full timer, compacting the indicators with respect to quality of the enclosed information is a necessity. The key measures of this win condition probably to have a small set of indicators based on observer's own priority selection. Just to give an example, from the IT system monitoring, our interview with a group of system administrators results that the group daily monitors eight to ten indicators, as to have more may overwhelm and mislead the observer's analysis.

(2) *Availability of layered performance metrics.* This second condition is the result of the first one, as in a project, we may start to monitor a higher level indicator and then go deeper for better understanding the nature of the development process or tracking back the symptoms of illness. We suggest to divide the metrics into three layers:

- the direct metrics, which is the lowest layer consisting of metrics directly obtained from the project repositories such as number of developer e-mail contributions, time stamps when a bug is resolved, the number of bug residing in the bug database, etc.;
- the indirect metrics, which is the aggregation of several direct metrics such as the average time to resolve bugs in certain time, average number of developer e-mail contribution in one semester, etc.; and
- the indicators, which is the highest level and provides comprehensive view of certain status of the project, e.g. the service delay within a release depicted as a function of the average time to respond and average time to resolve of bugs for the release. Figure 2 shows the examples of retrieving health indicators from a hierarchy of metrics.

(3) *Early availability of time relevant project information status.* The third win condition is to have quality information in a short time, as the project indicators reflect the current status which is not merely historical data. Time relevant information will give more accurate indication of the project, and if the project is considered unhealthy, appropriate treatments can be applied to change the project into healthy one before it is too late or getting worse. To get valid information status, the project manager should set a retrieval time constraints for each indicator he wants to monitor, i.e. within hours, days, or months.

The stakeholder values vary based on the stakeholder roles, domain of the project applications and the project scales. The value elicitation will define the selection of to-be-monitored health indicators to assess the project health status.

4. Evaluation process

This section describes the evaluation process of the health indicator concepts and the initial empirical result from some projects under the Apache umbrella.

We apply the proposed health indicators to four cases of large-matured Apache web-engineering projects indicated by more than 20 contributors (core and peripheral developers) per project which three times outsized the average number of developer in

most of OSS projects (Manenti *et al.*, 2005) and has already, at least, one major release (1.x, 2.x, etc.). The set consists of two well known Apache projects (Tomcat V.5 and HTTP Server/HTTPD V.2), and two challenged projects (Xindice and Slide). We focused our evaluation process on the two health indicators: the proportion of developers' participation and the bug service delay. As described in Section 3, these indicators are very worth noted by a project manager to assure that a project is still actively running and both indicators are simple to be evaluated.

4.1 The origin of the four projects

(1) Apache Tomcat (http://tomcat.apache.org/, accessed February 20, 2007) is a servlet container that is used in the official reference implementation for the Java Servlet and Java Server Pages technologies whose code base and specifications are donated by Sun under the Java Community Process in 1999. The first Apache release was Version 3.0. Since, then, multiple volunteers from Sun and numerous other organizations have contributed to the product. Currently, Tomcat has several major releases, employs 17 active committers and more than 50 emeritus committers. In 2005, Tomcat became its own top-level Apache project and powered numerous industries and organizations such as Wall Mart and General Motors. A survey by TheServerSide.com (www.theserverside.com/, accessed January 10, 2007) pointed Tomcat as one among the market leaders in its application domain.

(2) Apache HTTP Server (http://httpd.apache.org/, accessed February 20, 2007) is an effort to develop and maintain an open-source HTTP server for modern operating systems including UNIX and Windows NT. The development started in 1994 when Brian Behlendorf and a number of users for internet servers which are developed by the National Center for Supercomputer Applications (NCSA) encountered the increasing frustration in getting NCSA to respond to their suggestion. They decided to collaborate and integrate patches to the NCSA server software. In August 1995, the group released Apache 0.8. Since, then, the product was called as Apache HTTPD. Later, it is well known as Apache HTTP server and has been the most popular web server on the internet since April 1996. The HTTP server project employs 56 core contributors and hundreds of peripheral contributors. The project latest release is the Version 2.2.4. Apache Tomcat and HTTP Server are considered successful large projects. Hence, by examining the dynamics of both project communities, we improve our knowledge about the indication of a healthy community.

(3) Apache Xindice (http://xml.apache.org/xindice/, accessed February 20, 2007) is a database tool designed from the ground-up for storing XML data or what is more commonly referred to as a native XML database. Xindice is the continuation of the project that used to be called the dbXML Core. The dbXML's source code was donated to the ASF in December 2001. During the development, the developer community consists of eight active committers, seven inactive and emeritus committers, and 19 contributors. Xindice has its first stable release of Version 1.0 around March 2002 and continues with several milestone releases, such as Version 1.1b4 at April 8, 2004.

(4) Apache Slide (http://jakarta.apache.org/slide/, accessed February 20, 2007) is part of the Apache Jakarta project. Slide is a content repository which can

serve as a basis for a content management system/framework and other purposes. The original Slide codebase (Slide 0.7) was donated by Intalio Inc. during May 2000. Slide has reached its maturity after release 1.x and 2.x. The project employs 14 active committers, 14 inactive/emeritus committers, 20 contributors and 3 project sponsors. However, after its 2.1 release (at December 26, 2004), the project seemed to be disposed, although we still recorded some activities in the developer mailing list. Our interview with OSS expert indicates that Apache Xindice and Slide are in difficulties. This case can be taken as a fine comparison to successful ones and reveal the symptom of illness of a project.

4.2 Evaluation process of the proposed health indicators

In an OSS project, the developer mailing list is the main collaborative communication tool, where everyone who wants to participate in the project development can observe or join in. In Apache projects, the e-mail archives commonly consist of three major contents: the notification of developer commits to the SVN, notification of bug status report (the change of bug state) as a developer may work on something for the bug, and development-related short messages/e-mail conversation, i.e. problem reports, solution recommendation, polling for opinions, and technical discussion. The proportion of the developer contribution can be measured from the ratio between number of e-mail conversation, SVN/CVS Commits and bug status reports. We addressed two questions for measuring the developer contribution:

(1) What is the ideal proportion of emails submitted to the-mailing list?

(2) Are there any correlations among developers' contribution components?

To answer the above-mentioned questions, we need to collect numerical data about some existing OSS projects. For the purpose, we developed a tool for mining the web-based developers mailing list (hosted by Mailinglist ARChive, MARC) of each selected project. The tool uses the approach of a wrapper which retrieves project data web pages and then parses them to extract the information required. It retrieves the e-mails data (sender, subject, thread, and time stamp) based on some given time interval as the input parameter. The whole outcome is represented as XML and then using XSLT is further transformed to finally result in performance metrics, such as number of e-mails, number of CVS commits and number of bug status changes. For each project, we select and examine 38 months of projects' life time with at least one major stable release. To support viewing the dynamics of the projects, these e-mails are then grouped into monthly archives and the proportion are calculated. We illustrate the ratio of developers' contribution over the time and compare the result between the successful projects and the challenged ones. Later, we choose Apache HTTPD as the role model of a healthy project and employs linear regression to figure out the correlation among e-mail conversation, code contribution and bug report status.

Additionally, a healthy project should employ proven bug management practices to reduce the service delay and offer fast bug response. In an OSS project, the community voluntarily plays significant role in the bug tracking, and resolve the financial barrier as in traditional project. Here, we address three questions for assessing bug management in a project:

(1) Is there any appropriate bug reporting and monitoring in place?

(2) Is there any appropriate rating of bugs?

(3) What is the distribution of response time and closure time of bug reports?

Apache Project has centralized it bugs tracking within repositories managed by GNATS and later moved to Bugzilla. The Bugzilla offers more features like transaction logs (history) and search facility either simple or advanced search on descriptive information of bugs. This makes the dynamics of bugs are relatively easy-to-trace. It is not surprising that Bugzilla became very popular and widely used by 550 projects or companies 10 (www.bugzilla.org/installation-list/, accessed February 25, 2007). This indicates that each Apache project being evaluated implements appropriate bug tracking tools.

In order to evaluate the performance of projects based on bug's statistics for one stable release of each project, we retrieve each project's bug reports, measure quantitative data items, and depict the result within one software major release. Unfortunately, some data needs pre-processing due to inappropriate or illegal values. The pre-processing steps involve: removing records indicated as "duplicated" in the resolution field and excluding records containing invalid date (either in the open-date or change-date).

We retrieved and examined CVS logs from the bug database of Apache Tomcat 5, HTTP Server 2.0, Xindice and Slide. Furthermore, in measuring the distribution of response time (Tr) and closure time (Tc) of bug reports, we formulate the calculation using the criteria:

- Tr is the length of time interval between open date and last change date for the bugs having status field set to "NEW" which means the bug is confirmed and accepted by the community for further processing; and
- Tc is time to resolve a bug, calculated by measuring the length of time interval between open date and last change for bugs having status "RESOLVED," which means the bug is already went through the development processes.

5. Initial empirical result

This section describes the initial empirical result which is composed of data collection from the four Apache projects and data analysis.

5.1 The developer contribution level

A study (Wahyudin *et al.*, 2006) found that in the two successful projects a positive trend line of developers' e-mail contributions during project life time exists (see Figure A1 in the Appendix). On the contrary, the two challenged projects reveals dying periods as revealed in the diminishing absolute number of developer contribution shown in the Figure A2 (in the Appendix). In this paper, we look further the cause of the illness symptoms and what a healthy relation should look like between components in the developer contributions.

5.1.1 Developers' contribution patterns in the four reviewed projects. To better understand the developer contribution patterns within different types of project, we examine the retrieved data set, and calculate the ratio between code contribution (number of CVS commits), and reports of bug status (number of bug status change notification)

with the developer e-mail conversations. We argue that in a healthy community the project should exhibit more proportional ratio among these metrics, i.e. every CVS commit ideally should be followed up by the developer discussion in the mailing list before inserted into the body of code. We found the both challenged projects exhibit more fluctuation and higher ratios as shown in Figure 3. It means, the developer community retrieved more notification of code contributions and bug reports but responded less in the mailing list. This situation may indicate illness symptoms. We considered some of the illnesses are the facts that the developer community pays less attention to project status' changes; the project employs small proportion of active developers which also signify developer demotivation which further needs to be investigated by experts in OSS community. On the contrary, both the HTTPD and Tomcat signify more reasonable proportion in the ratio of developer contribution. This can be interpreted that most of the developer contributions triggered some responses from the developer community.

5.1.2 Email conversation as a function of CVS/SVN commits and bug status changes. As described above, a successful project community exhibits more normal distribution of developer activities metrics during the development process. The next step, we want to find out the correlation among these metrics. For the purpose, we perform a regression model analysis. We use the data set retrieved from Apache HTTPD as the role model. We assume that the result will suggest the correlation of developer contribution metrics in a healthy project. The data set retrieved from HTTPD consist of 38 months of observation, with the total of 15,781 e-mail conversations ($\mu = 415.2$; $\delta = 135.9$), 14,199 SVN/CVS commits ($\mu = 373.6$; $\delta = 99.4$), and 8,757 bug status

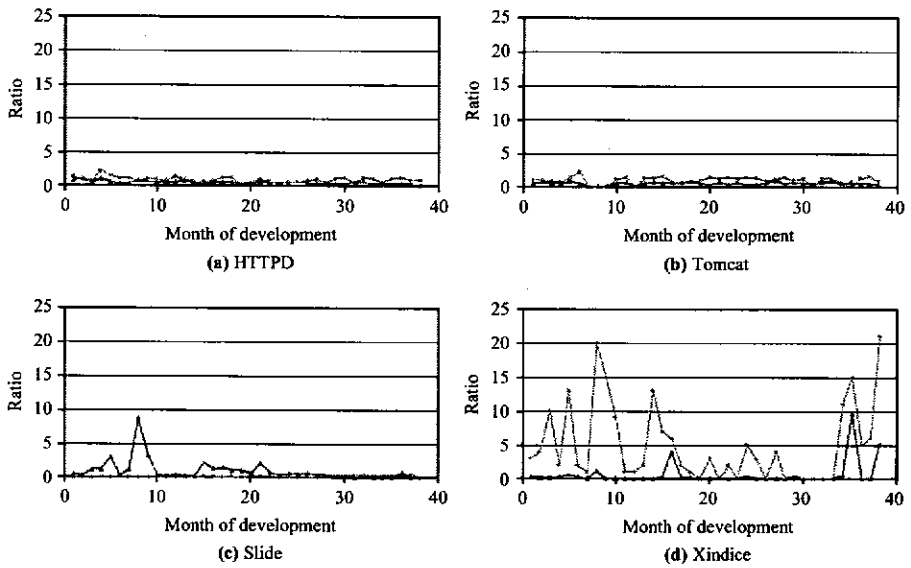


Figure 3.
Developers' contribution patterns

Notes: In the healthy projects (3(a) and 3(b)) the number of code contributions per developer email and the number of bug status report per developer email tend to be proportional. On the contrary, the challenged projects (3(c) and 3(d)) show fluctuations which signify the imbalance between code contributions/developer email submissions and bug status reports/developer email submissions

changes ($\mu = 230.4$; $\delta = 106.1$)[1]. To observe more relationships among the measures, we employ the regression linear analysis, and model the developer e-mail contribution as a function:

$$Y = b_0 + b_1 X_1 + b_2 X_2 + \varepsilon \quad (1)$$

Where Y is number of e-mail conversation, X_1 is number of CVS commits and X_2 is number of bug status changes. The confidence interval of our test is 95 percent. The test consist of two phases: first we test the significance of the regression coefficients of our model to find out the impact of CVS commits and bug status changes to the number of e-mail conversation, second we test the regression model itself to assess its validity.

5.1.2.1 Regression coefficients significance analysis. The statistics test for hypothesis of each coefficient regression is the Student's t-test which can be calculated as:

$$t_0 = \frac{\hat{b}_i}{\sqrt{\hat{\sigma}^2 C_{ii}}} \quad (2)$$

where C_{ii} is the diagonal matrix element which correlated with $\hat{b}_i$

We calculate the model using SPSS and test the following hypothesis:

H_0. coefficient regression is not significant

H_1. coefficient regression is significant

The analysis will reject H_0 if:

$$|t_0| > t_{\alpha/2,n-2} \quad (3)$$

where $t_{\text{table}} = t_{0.025,36} = 1.960$:

- *Constants.* The calculation results t_0 3.673 for the constant. Since, $3.673 > 1.960$ H_0 is rejected. This means that the constant has significant impact to the regression model.
- *CVS commits.* The calculation results t_0 4.715 for CVS Commits. As $4.715 > 1.960$ H_0 is rejected. This means the bug status changes has significant impact to the number of conversation e-mail.
- *Bug status changes.* The calculation results $t_0 - 0.537$ for the bug status changes. Since, $-0.537 < 1.960$, H_0 is not rejected.

This means although bug development is an important issue in OSS project, however the bug report status has less and does not show significant impact for triggering developer conversations in developer mailing list.

5.1.2.2 Regression model significance analysis. We employ the F-test for analyzing the proposed model, which can be calculated as:

$$F_0 = \frac{MS_R}{MS_E} \quad (4)$$

We calculate the model using SPSS and test following hypothesis:

H_0. regression model is not significant; and

H_1. regression model is significant.

The analysis will reject:

$$F_0 > F_{\alpha,n-2} \tag{5}$$

where F_{table} or $F_{0.05,36} = 4.11$.

The calculation results $F_0 = 11.975$. Since, $11.975 > 4.11$, H_0 is rejected. The test concludes that the model is valid and there is a linear relationship between e-mail conversations with CVS Commits.

The above results conceal that in a healthy project (such as HTTPD) the code contribution has significant impact to amplify the number of e-mail conversations in the developer mailing list such that the ratio between these two variables are kept in proportional during the development process which signifies one healthy status. The bug status reports are also important to illustrate the project service throughput. However, we suggest that monitoring the dynamics of the bug status report should be further correlated with other variables in the bug tracking activities such as the number of bug per reporter, bug response per reviewer, bug assignment per contributor, service delay (response and Tc), validation time, etc. which we will cover in our future work as other types of project health indicator.

5.2 The (bug) service delay

Based on the measurement scenario on bug service delay as mentioned in Section 4, we present these following quantitative results. The first measurement is to see the distribution of the bugs' severity on each project. In the Apache projects, the bugs are categorized based on their severities related to security (critical) and fault (blocker), related to feature (major, minor, enhancement, and normal) and related to cosmetic works (regression and trivial). Later, for further processing, the community put the development priority (P1-P5) for each bug, where the P1 means the top priority and needs to be resolved as soon as possible.

We retrieved the bug data from Apache Tomcat 5 (2891 bugs), HTTPD 2 (3,663 bugs), Xindice (152 bugs) and Slide (420 bugs). On the data, we examine the distribution of the bugs based on severity and priority to find the proportion of bug assignment. We observe also a situation that the distribution of the bugs based on severity is almost "normal" as illustrated in Table I (see the figures in italic), in the sense that most of the bug reports coming from the user community are feature requests, functionality errors or decorative ones. Furthermore, from the tables, we can see that although the user-community reports bugs and considers the bugs of high severity (such as "blocker"), the priority assignment by developer does not always follow the "user needs". In other words, the developer does not always assign high severity (according to user) with high priority.

To measure the performance of bug service delay in a project, we measure the bug Tr (time to respond) and the bug Tc (time to resolve). We categorized such service delay into several time interval scales as shown in the Table II. Figure 4 shows the distribution of bug Tr and bug Tc from the four reviewed projects. From the figure, it is obvious that Tomcat has the most responsive community, as 60 percent of the reported bugs are responded less than seven days, 79 percent are responded within 100 days. On the other hand, Xindice exhibits poor performance as the majority of the bug reports (72 percent) were responded by the community in more than 100 days.

The successful projects provide faster service as their bug Tcs are shorter compared to those of Xindice and Slide. The results are about 46 percent of the bugs in Tomcat and 59 percent of the bugs in HTTPD are resolved within 100 days, while most of the

Table I.
Bug priority distribution per severity

Regression	0.0	0.2	0.0	0.0	0.0						0.0	0.5	0.0	0.0	0.0						
Trivial	0.0	0.7	0.1	0.2	0.5	0.0	0.2	0.0	0.0	0.0	0.1	0.5	0.1	0.1	0.2	0.0	0.7	0.7	0.0	0.0	

bugs reported for the challenged projects are resolved within or more than a year. However, our result also found intriguing fact that more than 20 percent of the bugs were resolved more than a year in HTTPD and Tomcat. We investigated this issue by measuring the absolute number of the resolved bugs and correlated with the assigned priority. For HTTPD, among the 999 resolved bugs, 24 percent are latent, since they were resolved more than a year; 88 percent of these latent bugs are categorized as lower priority (P3-P5) and 45 percent are considered as cosmetic work or minor feature error. For Tomcat, from 2,063 resolved bugs, 27 percent are latent bugs with only 9 percent of top priority bugs (P1 and P2), and less than 15 percent are severe bugs (critical and blocker). We conclude that in both successful projects, the community offers faster response to a bug with higher priority, and tends to delay the less important ones.

6. Discussion

For many OSS developers, challenge is what really motivates them and it makes the project more active. Once they are drawn to a problem, they feel that they could create a better solution themselves, rather than using the existing ones. Over the time, the projects may evolve and so does the motivation of the developer.

Our study in OSS project community health revealed two extreme trend lines in the developer participation:

(1) lively developers' activity as shown by Tomcat and HTTPD; and

(2) non responsive or dying developers' community, which we observed in Xindice and Slide.

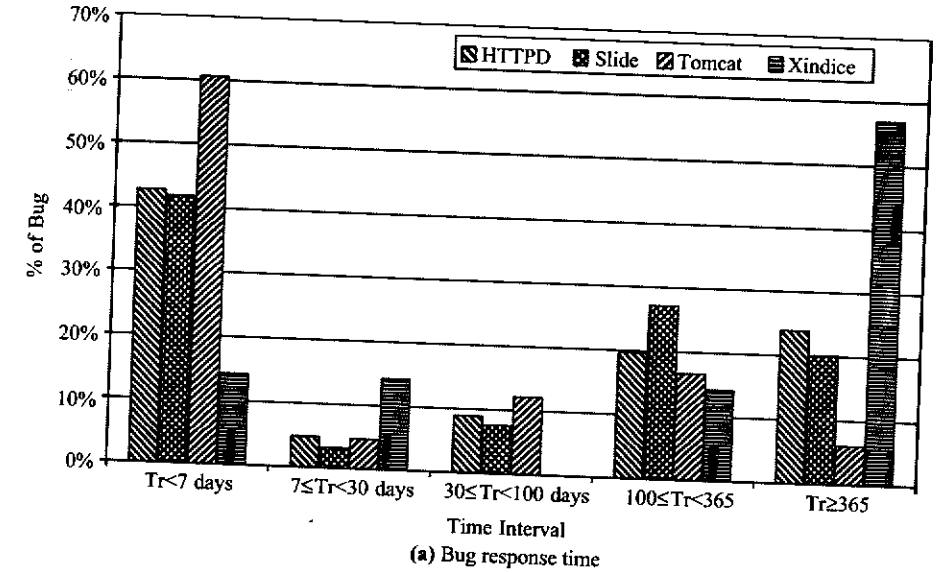
The developer community in the challenged projects shows less normal proportion of developers' contribution metrics (such as CVS commit, bug change status and e-mail conversation). This condition is considered to signify situation in which the community is less responsive to the status changes within the project. In a healthy project, such as HTTPD, we found a correlation between CVS commits with the e-mail conversations in the developer's mailing list. This indicates that, in general, a contribution of code or document into project repositories may attract other developers to interactively involve in discussions and reviews.

Xindice obviously reveals a very fluctuating proportion of developer contribution (see Figure 3(d), which means that there are significant imbalances between the contribution and the response from the developers' community). Furthermore, based on the absolute number of the developers' contribution, Xindice indicates a "dying" project, which can be seen in Figure A2. In its last 33 months, the developers' contribution levels were low compared to its first five months under observation. When we discussed with some experts, according to them, the reasons behind the condition are:

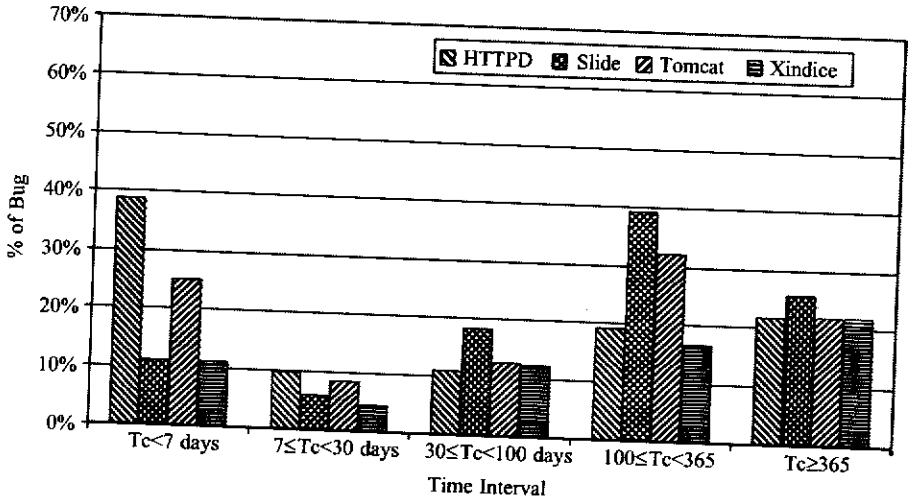
- Xindice has been abandoned by its key developer, which also proves that diversity of core developers is important; and

Table II.
Interval scales for bug time to respond and time to resolve

	Interval scales for bug service delay				
	Less than a week	In weeks	Less than 100 days	Less than a year	In years
Range (days)	$0 <= t < 7$	$7 <= t < 30$	$30 <= t < 100$	$100 <= t < 365$	Days $t > 365$



(a) Bug response time



(b) Bug closure time

Note: A Healthy project should be more responsive to bug report and offer faster bug resolution time

Figure 4.
Bug service time distribution for reviewed projects

- the changes of market demand and technology trend caused the developers' community to recognize that proposed plan and the results not to evolve expected.

Slide has a different story as shown in Figure 3(c). The project exhibits proportional developer contribution, however based on the result of measuring the absolute number, on the beginning Slide was very promising, but since October 2004, the project was hit by catastrophic illness indicated by the decrement of its developer contributions (Figure 6).

The experts participating in the Slide project mentioned that Slide was once in a dormant state. The project woke up after a talented expert got involved in November 2003, and significantly contributed for the peak performance of Slide. However, after several months, he decided to leave the project, leading to the collapse of Slide. A study on this case (Wahyudin *et al.*, 2006) validated this statement by measuring this experts' mail conversation and suggest the fluctuation in developers' mail follows the dynamics in "The Expert" mails. Around March 2004, as the expert decided to leave the project, Slide developers' mailing list still showed notable activity for several months, before their number finally collapsed. Our observation in February 2007 disclosed although there are still some developer activities, the level is relatively low compared to the zenith period when "the Expert" was still actively involved in the project.

Our study also reveals that a healthy community will be more responsive and more eager to resolve issues or bugs introduced to them. However, the empirical result of bug severity distributions argued that the more severe bug does not always mean to be of higher priority, since most of the top-priority bugs are the normal ones as shown in Figure 1. It is likely that the Tr is affected also by priority set by developers due to some consideration. For example, a blocker might be given lower priority when it occurs very rarely and it is planned not to be resolved in the current release. This practice exhibits value tradeoffs between the users who report the bug, assign the bug severity and expecting quick response, with the community who assess, assign, develop and resolve the bug.

7. Conclusions and future work

Managing and monitoring health in OSS projects is a complex challenge, due to the typical characteristics of OSS development model. Important indicators such as activity of developers and performance of bugs' management are easier to measure as they have become part of the development nature itself. However, for the comprehensive determination of health measurement one has to consider other indicators which needs be formulated and further explored.

Some of these to-be-formulated indicators are"hidden" behind the development process. Hence, effectively, it is the core stakeholder who should make the decision about which indicators should be employed, based on the projects initial needs. In principle, our approach is applicable for commercial web-engineering project. However, further work should investigate the commercial project structure and the culture within the team development to reveal appropriate health indicators.

The investigation of important health indicators is just the beginning. The next step is the development of assessment methods that allow observers to get semi-quantitative measures of project health itself. This will help people to learn how these processes work in-depth, allow to enhance cooperation and give monitoring and "early-warning" capabilities to the project stakeholders. Nevertheless, more works should be done to define relevant dynamics indicators, empirical rules and measurement metrics for an on going OSS project quality and project community assessment.

Note

1. We use μ to represent monthly average and δ for its standard deviation.

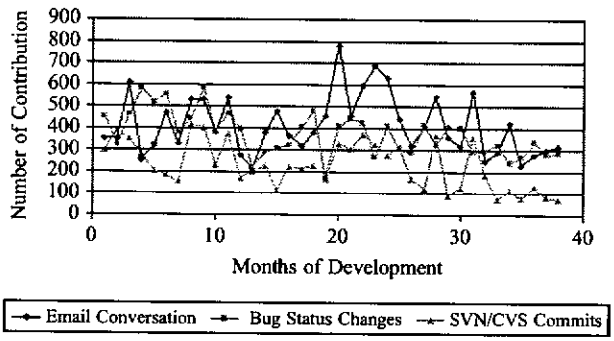
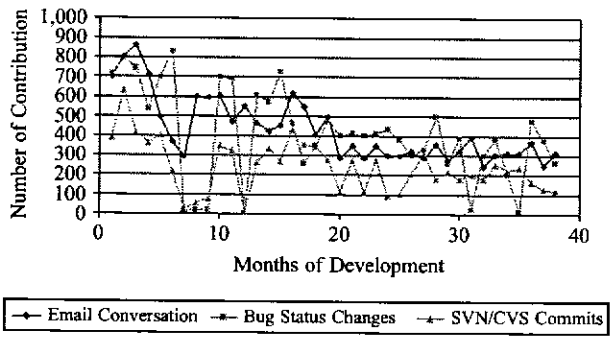
Appendix. Developer contribution absolute number

Figures A1 and A2 show the absolute number of developer contribution within 38 months of development of the reviewed projects. The developers' contribution patterns are distinguished

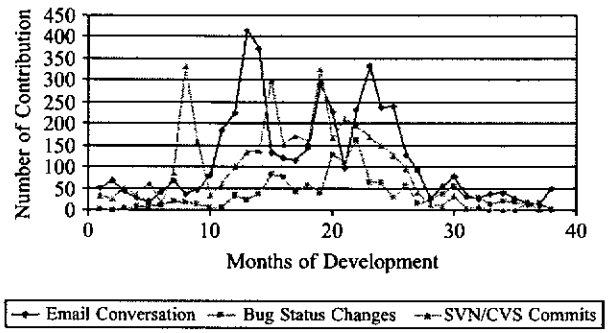


(a) HTTPD

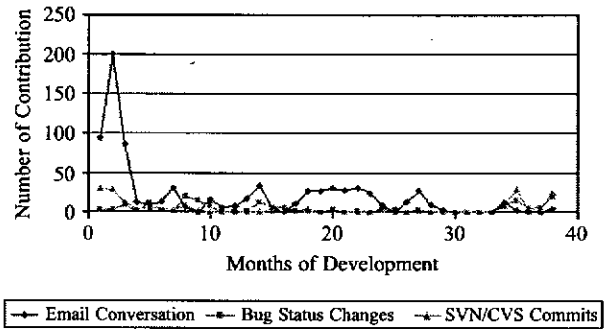


(b) Tomcat

Figure A1.
Absolute number of developer contribution in the successful OSS projects (HTTPD and Tomcat)



(a) Slide



(b) Xindice

Figure A2.
Absolute number of developer contribution in the challenged OSS projects (Xindice and Slide)

into three-line categories: the code contribution (number of SVN/CVS commit), the bug status report (number of bug status changes in the bugzilla), and the developer e-mail conversation (number of e-mail submitted into the developer mailing list).

In healthy project, such as Apache HTTPD and Tomcat (Figure A1), the developer communities are very dynamics with high level of contribution. In contrary, both the challenged projects (Figure A2) face diminishing developer activity, especially in Xindice which can be considered as a dying project.

Editorial objectives

The aim of the *International Journal of Web Information Systems* is to be a source for Web Information Systems research and development, and to serve as an outlet for facilitating communication and networking among Web Information Systems researchers and professionals across academics, government, industry, researchers, and students.

Editorial scope

IJWIS aims to publish and disseminate knowledge on an international basis in the area of Web Information Systems. It is published four times a year, with the purpose of providing a forum for state-of-the-art developments and research, as well as current innovative activities in Web information systems.

The reviewing process

Each paper submitted is subjected to the following review procedures:

(1) It is reviewed by the editor for general suitability for this publication.
(2) If it is judged suitable two reviewers are selected and a double blind review process takes place.
(3) Based on the recommendations of the reviewers, the editor then decides whether the particular article should be accepted as it is, revised or rejected.

Emerald Literati Editing Service

The Literati Network can recommend the services of a number of freelance copy editors, all themselves experienced authors, to contributors who wish to improve the standard of English in their paper before submission. This is particularly useful for those whose first language is not English. www.emeraldinsight.com/editingservice

Manuscript requirements

All initial submissions should be made as electronic attachments to the editors at ijwis@iiwas.org The manuscripts should be submitted in double line spacing with wide margins. All authors should be shown and **author's details** must be on a separate page and the author should not be identified anywhere else in the article.

Articles are not restricted to a certain length. However, articles of 2,500 words or more are considered appropriate. Shorter contributions may be considered. A brief **autobiographical note** should be supplied including full name, affiliation, e-mail address and full international contact details. Authors must supply a **structured abstract** set out under 4-6 sub-headings: Purpose; Methodology/approach; Findings; Research limitations/implications (if applicable); Practical implications (if applicable); and the Originality/value of paper. Maximum is 250 words in total. In addition provide up to six **keywords** which encapsulate the principal topics of the paper and categorise your paper under one of these **classifications**: Research paper, Viewpoint, Technical paper, Conceptual paper, Case study, Literature review or General review. For more information and guidance on structured abstracts visit: www.emeraldinsight.com/structuredabstracts

Where there is a **methodology**, it should be clearly described under a separate heading. **Headings** must be short, clearly defined and not numbered. **Notes** or **Endnotes** should be used only if absolutely necessary and must be identified in the text by consecutive numbers, enclosed in square brackets and listed at the end of the article.

All **Figures** (charts, diagrams and line drawings) and **Plates** (photographic images) should be submitted in both electronic form and hard copy originals. Figures should be of clear quality, in black and white and numbered consecutively with arabic numerals.

Figures created in MS Word, MS PowerPoint, MS Excel, Illustrator and Freehand should be saved in their native formats.

Electronic figures created in other applications should be copied from the origination software and pasted into a blank MS Word document or saved and imported into a MS Word document by choosing "Insert" from the menu bar, "Picture" from the drop-down menu and selecting "From File ..." to select the graphic to be imported.

For figures which cannot be supplied in MS Word, acceptable standard image formats are: .pdf, .ai, .wmf and .eps. If you are unable to supply graphics in these formats then please ensure they are .tif, .jpeg, or .bmp at a resolution of at least 300dpi and at least 10cm wide.

To prepare screenshots, simultaneously press the "Alt" and "Print screen" keys on the keyboard, open a blank Microsoft Word document and simultaneously press "Ctrl" and "V" to paste the image. (Capture all the contents/windows on the computer screen to paste into MS Word, by simultaneously pressing "Ctrl" and "Print screen".)

For photographic images (plates) good quality original photographs should be submitted. If supplied electronically they should be saved as .tif or .jpeg files at a resolution of at least 300dpi and at least 10cm wide. Digital camera settings should be set at the highest resolution/quality as possible.

In the text of the paper the preferred position of all tables, figures and plates should be indicated by typing on a separate line the words "Take in Figure (No.)" or "Take in Plate (No.)". Tables should be typed and included as part of the manuscript. They should not be submitted as graphic elements. Supply succinct and clear captions for all tables, figures and plates. Ensure that tables and figures are complete with necessary superscripts shown, both next to the relevant items and with the corresponding explanations or levels of significance shown as footnotes in the tables and figures.

References to other publications must be in Harvard style and carefully checked for completeness, accuracy and consistency. This is very important in an electronic environment because it enables your readers to exploit the Reference Linking facility on the database and link back to the works you have cited through CrossRef. You should include all author names and initials and give any journal title in full.

You should cite publications in the text: (Adams, 2006) using the first named author's name or (Adams and Brown, 2006) citing both names of two, or (Adams *et al.*, 2006), when there are three or more authors. At the end of the paper a reference list in alphabetical order should be supplied:

For books: surname, initials, (year), *title of book*, publisher, place of publication, e.g. Harrow, R. (2005), *No Place to Hide*, Simon & Schuster, New York, NY.

For book chapters: surname, initials, (year), "chapter title", editor's surname, initials, *title of book*, publisher, place of publication, pages, e.g. Calabrese, F.A. (2005), "The early pathways: theory to practice – a continuum", in Stankosky, M. (Ed.), *Creating the Discipline of Knowledge Management*, Elsevier, New York, NY, pp. 15-20.

For journals: surname, initials, (year), "title of article", *journal name*, volume, number, pages, e.g. Capizzi, M.T. and Ferguson, R. (2005), "Loyalty trends for the twenty-first century", *Journal of Consumer Marketing*, Vol. 22 No. 2, pp. 72-80.

For electronic sources: if available online the full URL should be supplied at the end of the reference.

Final submission of the article

Once accepted for publication, the editor may request the final version as an attached file to an e-mail or to be supplied on a **CD-ROM** labelled with author name(s); title of article; journal title; file name.

Each article must be accompanied by a completed and signed **Journal Article Record Form** available from the Editor or on www.emeraldinsight.com/jarform

The manuscript will be considered to be the definitive version of the article. The author must ensure that it is complete, grammatically correct and without spelling or typographical errors.

The preferred file format is Word. Other acceptable formats for technical/maths content are Rich text format.

Technical assistance is available by contacting Mike Massey at Emerald. E-mail: mmassey@emeraldinsight.com

Authors' Charter

This highlights some of the main points of our Authors' Charter. For the full version visit: **www.emeraldinsight.com/charter**

Your rights as an author

Emerald believes that as an author you have the right to expect your publisher to deliver:

- An efficient and courteous publishing service at all times
- Prompt acknowledgement of correspondence and manuscripts received at Emerald
- Prompt notification of publication details
- A high professional standard of accuracy and clarity of presentation
- A complimentary journal issue in which your article appeared
- Article reprints
- A premium service for permission and reprint requests
- Your moral rights as an author.

Emerald represents and protects moral rights as follows:

- To be acknowledged as the author of your work and receive due respect and credit for it
- To be able to object to derogatory treatment of your work
- Not to have your work plagiarized by others.

The Emerald Literati Network

The Emerald Literati Network is a unique service for authors which provides an international network of scholars and practitioners who write for our publications. Membership is a free and unique service for authors. It provides:

- A dedicated area of the Emerald web site for authors
- Resources and support in publishing your research
- Free registration of yourself and your work, and access to the details of potential research partners in Emerald Research Connections
- The opportunity to post and receive relevant Calls for Papers
- Information on publishing developments
- Awards for outstanding scholarship
- Usage information on authors, themes, titles and regions
- Access to tips and tools on how to further promote your work
- Awards for Excellence.
