ABSTRACT

We propose a compressive method for tracking doubly selective channels within multicarrier systems, including OFDM systems. Using the recently introduced concept of modified compressed sensing (MOD-CS), the sequential delay-Doppler sparsity of the channel is exploited to improve estimation performance through a recursive estimation mode. The proposed compressive channel tracking algorithm uses a MOD-CS version of OMP with reduced complexity. Simulation results demonstrate substantial performance gains over conventional compressive channel estimation.

Index Terms—OFDM, multicarrier modulation, channel estimation, compressed sensing, sparsity.

1. INTRODUCTION

Many wireless channels tend to be dominated by a relatively small number of clusters of significant paths [1]. This inherent sparsity is exploited by compressive channel estimation [2, 3], which makes use of compressed sensing (CS) recovery algorithms like basis pursuit denoising (BPDN) [4] or orthogonal matching pursuit (OMP) [5]. In this paper, we propose a compressive pilot-aided scheme that performs a time-sequential (recursive) estimation, or tracking, of doubly selective channels. We consider pulse-shaping multicarrier (MC) systems, which include OFDM systems as a special case.

The proposed compressive channel tracking method is based on the recently introduced concept of modified compressed sensing (MOD-CS), which assumes that a part of the support of the signal to be estimated is known a priori [6, 7]. In our application of MOD-CS, the prior support information is given by the effective delay-Doppler support estimated during the previous symbol block. This is justified by the fact—demonstrated in this paper—that in typical scenarios, the delay-Doppler support changes only slowly.

A MOD-CS variant of BPDN was proposed in [7]. However, motivated by certain practical advantages of OMP over BPDN [8], we will use a MOD-CS variant of OMP, previously described in [9], which we term the modified OMP (MOD-OMP) algorithm. The complexity of MOD-OMP is typically lower than that of OMP.

This paper is organized as follows. The MC system model is recalled in Section 2. In Section 3, we review some MOD-CS fundamentals and state the MOD-OMP algorithm. The MOD-CS-based channel tracking method is presented in Section 4. Section 5 investigates the channel’s delay-Doppler sparsity for consecutive symbol blocks. Finally, simulation results demonstrating the achieved performance gains are presented in Section 6.

2. MULTICARRIER SYSTEM MODEL

We assume that Q consecutive symbol blocks of L MC symbols each are transmitted using a pulse-shaping MC system with K subcarriers.

3. MODIFIED COMPRESSED SENSING

A vector is said to be S-sparse if at most S of its entries are nonzero, i.e., if its support $S$ satisfies $|S| \leq S$. In a typical CS reconstruction setting, an (approximately) S-sparse vector $x \in \mathbb{C}^{M_1}$ is to be estimated from a known vector $y \in \mathbb{C}^{M_2}$, based on the linear model

$$y = \Phi x + z,$$  

where $\Phi \in \mathbb{C}^{M_2 \times M_1}$ is a known measurement matrix and $z \in \mathbb{C}^{M_2}$ is an unknown noise vector. Usually, $M_2 \ll M_1$. Two major approaches to solving this problem are algorithms using convex optimization techniques, like BPDN [4], and greedy algorithms, like OMP [5]. Convex optimization algorithms tend to offer better theoretical performance guarantees, whereas greedy algorithms often yield faster implementations and better results in practice.

In some applications, a part $\mathcal{R} \subseteq S$ of the support of $x$ is known a priori. An adaptation of BPDN called modified BPDN (MOD-BPDN) [7] exploits this information by solving the problem

$$\min_{x' \in \mathbb{C}^{M_1}} \|x'\|_0 \quad \text{subject to} \quad \|y - \Phi x'\|_2 \leq \epsilon,$$

where $x'_{\mathcal{R}}$ is the restriction of $x'$ to $\mathcal{R}$, the complement of $\mathcal{R}$ within $\{1, \ldots, M_1\}$. MOD-BPDN satisfies desirable performance guarantees [7]. However, in view of certain practical advantages of OMP over BPDN [8], we will here consider a variant of OMP that we call modified OMP (MOD-OMP), and which was described in [9]. In an initialization step, the signal is reconstructed on the known support subset $\mathcal{R}$, and afterwards regular OMP steps are performed on $\mathcal{R}$ until a stopping criterion is met. A detailed statement of the MOD-OMP algorithm is as follows.

- **Input**: $y$, $\Phi$, $\mathcal{R}$, $S$, and target error power level $\rho^2$.

- **Initialization**: Solve the least squares (LS) problem
  $$x_0 = \arg \min_{x' : \|x'\|_0 = 0} \|y - \Phi x'\|_2^2;$$
  calculate the residual $r_0 = y - \Phi x_0$; set $\mathcal{S}_0 = \mathcal{R}$ and $s = 0$.

- **OMP steps**: While $s < |S| - |\mathcal{R}|$ and $\|r_s\|_2 > \rho \|y\|_2$.
  1. increment $s \leftarrow s + 1$;
  2. find $\ell = \arg \max_{\mathcal{R}} \| \Phi_{\mathcal{R}} r_{s-1} \|$; set $\mathcal{S}_s = \mathcal{S}_{s-1} \cup \{\ell\}$;
  3. solve the LS problem $x_s = \arg \min_{x' : \|x'\|_0 = 0} \|y - \Phi x'\|_2^2$;
  4. calculate the new residual $r_s = y - \Phi x_s$.

- **Output**: Signal estimate $\hat{x} = x_s$.

By an extension of the analysis for OMP in [15], performance guarantees for MOD-OMP in terms of the restricted isometry constant [8, 15, 16] can be shown (omitted here because of limited space; see also [9]). Conventional CS—i.e., no prior partial information about the signal support—corresponds to $\mathcal{R} = \emptyset$; hence, both MOD-BPDN and MOD-OMP coincide with their CS counterparts in this case. As $\mathcal{R}$ approaches $S$, fewer OMP steps are required, and thus the computational complexity of MOD-OMP is reduced. It follows that MOD-OMP has a lower complexity than OMP.

If the prior partial-support information $\mathcal{R}$ is only approximate, the initialization of MOD-OMP can be modified as follows. Let $\tilde{x} \triangleq \arg \min_{x' : \|x'\|_0 = 0} \|y - \Phi x'\|_2$, and define the subset $\tilde{\mathcal{R}} \subseteq \mathcal{R}$ consisting of those elements of $\mathcal{R}$ for which the magnitudes of the entries of $\tilde{x}$ are above a given threshold. We then propose to use the subset $\tilde{\mathcal{R}}$ instead of $\mathcal{R}$ for initializing MOD-OMP.

4. COMPRESSION CHANNEL TRACKING

We will now describe the proposed channel tracking method. This method generalizes the CS-based estimator of [2], as a consequence, the following development is initially parallel to that in [2].

For practical (underspread [12, 13]) channels and practical transmit and receive pulses, the coefficients $F_{\ell, q}^{(\ell)}$ in (4) are effectively supported in a small rectangular region about the origin, $[0, D - 1] \times [-J/2, J/2 - 1]$, where $D \leq K$, $J \leq L$ is assumed even, and $D$ and $J$ are chosen such that $\Delta K = K/D$ and $\Delta L \leq L/J$ are integers. Because of (3), the channel coefficients $H_{\ell, q}^{(\ell)}$ are then determined by their values on the subsampled grid $\mathcal{G} \triangleq \{(l, k) = (\ell \Delta L, \kappa \Delta K) : \ell = 0, \ldots, D - 1, \kappa = 0, \ldots, D - 1\}$, and we have

$$H_{\lambda, \nu}^{(q)} = \sum_{m = 0}^{D - 1} \sum_{j = -J/2}^{J/2 - 1} F_{m, i}^{(q)} e^{-j2\pi (\frac{m\nu}{M_1} - \frac{j\lambda}{M_2})}.$$  

In [2], it has been shown for a simple channel model that the 2D DFT coefficients $F_{m, l}^{(q)}$ (for $q$ fixed) are approximately sparse, with the sparsity level limited by leakage effects. To mitigate these leakage effects and thereby enhance the sparsity, we generalize (6) to an orthonormal 2D basis expansion

$$H_{\lambda, \nu}^{(q)} = \sum_{m = 0}^{D - 1} \sum_{j = -J/2}^{J/2 - 1} a_{m, l}^{(q)} u_{m, i}[\lambda, \nu].$$  

A “sparsity-enhancing” construction of the basis $\{u_{m, i}[\lambda, \nu]\}$ has been proposed in [2]. We assume that the coefficient functions $a_{m, l}^{(q)}$ are approximately $S$-sparse, with $S \leq JD$. We can rewrite (7) as

$$h_j^{(q)} = U \alpha_j^{(q)},$$  

where $h_j^{(q)} = \text{vec}_{\lambda, \nu} \{H_{\lambda, \nu}^{(q)} \} \in \mathbb{C}^{JD}$ (i.e., $h_j^{(q)} = \{h_{1, j}^{(q)} \ldots h_{JD, j}^{(q)}\}^T$) with $h_{\ell, j}^{(q)} = H_{\ell, \ell}^{(q)}$ and $H_{\lambda, \nu}^{(q)}$ is a unitary matrix whose $(i + J/2 + m + 1, l + \lambda, k + \kappa)$th column is given by the vector $\{u_{m, i}[\lambda, \nu]\}$, and $\alpha_j^{(q)} = \text{vec}_{m, l} \{a_{m, l}^{(q)}\} \in \mathbb{C}^{JD}$.

For pilot-aided channel estimation, pilot symbols $\delta_{l, k}^{(q)} = p_{l, k}^{(q)}$ are transmitted at time-frequency positions $(l, k) \in \mathcal{G}$, where $\mathcal{P}^{(q)} \subseteq \mathcal{G}$. The receiver then calculates channel estimates $\hat{H}_{l, k}^{(q)} = \frac{1}{\gamma_{l, k}^{(q)}} h_{l, k}^{(q)}$ at the pilot positions $(l, k) \in \mathcal{P}^{(q)}$. Reducing (8) to these pilot positions yields $h_j^{(q)} = U \alpha_j^{(q)}$, which involves the corresponding length-$|\mathcal{P}^{(q)}|$ subvector $h_j^{(q)}$ of $h_j^{(q)}$ and the corresponding $|\mathcal{P}^{(q)}| \times JD$ submatrix $U^{(q)}$ of $U$. Scaling the columns of $U^{(q)}$ so that they have unit $\ell_2$-norm,

$$h_j^{(q)} = U \alpha_j^{(q)} D^{(q)}$$  

with a nonsingular diagonal matrix $D^{(q)}$, and

$$\hat{H}_{l, k}^{(q)} = \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} h_{l, k}^{(q)} = \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}},$$

using (2) to these pilot positions yields $h_j^{(q)} = U \alpha_j^{(q)}$, which involves the corresponding length-$|\mathcal{P}^{(q)}|$ subvector $h_j^{(q)}$ of $h_j^{(q)}$ and the corresponding $|\mathcal{P}^{(q)}| \times JD$ submatrix $U^{(q)}$ of $U$. Scaling the columns of $U^{(q)}$ so that they have unit $\ell_2$-norm, and

$$\hat{H}_{l, k}^{(q)} = \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} h_{l, k}^{(q)} = \frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} h_{l, k}^{(q)},$$

yielding the vector with entries $\frac{1}{\gamma_{l, k}^{(q)}} \frac{1}{\gamma_{l, k}^{(q)}} h_{l, k}^{(q)} \in \mathcal{P}^{(q)}$. This equation is of the form (5), with dimensions $M_2 \triangleq |\mathcal{P}^{(q)}|$ and $M_1 = JD$.
In practice, $M_2 \ll JD$. Since the expansion coefficients $a_{m,i}^{(q)}$ were assumed to be sparse, the vector $x^{(q)}$ is sparse, too. Therefore, one could use a CS recovery algorithm like BPDN or OMP to obtain an estimate of $x^{(q)}$ from $y^{(q)}$ based on (9). This would correspond to conventional compressive channel estimation as in [2].

Here, we propose a different approach. As shown in Section 5, the supports of two coefficient DFT functions $F_{m,i}^{(q)}$ and $F_{m,i}^{+1}$ overlap to an extent that depends on the spatial geometry and the velocities of transmitter, receiver, and scatterers. Thus, if the DFT basis $\{ u_{m,i}^{q} [\lambda, \kappa] \} = \sum_{p=1}^{P} e^{-2\pi i (\lambda/2p + \kappa/2t)}$ is used, $x^{(q)}$ and $x^{(q+1)}$ have overlapping supports. Simulation studies demonstrate that this is still true if $\{ u_{m,i}^{q} [\lambda, \kappa] \}$ is optimized as described in [2].

This motivates the following channel tracking method, which we describe for a general basis $\{ u_{m,i}^{q} [\lambda, \kappa] \}$. For the first symbol block $(q = 0)$, we use conventional compressive channel estimation as discussed above to obtain an estimate $\hat{x}^{(0)}$ of $x^{(0)}$. After scaling $\hat{x}^{(0)}$ with $D^{(0)}$, we obtain an estimate $\hat{a}^{(0)} = D^{(0)} \hat{x}^{(0)}$ of $\alpha^{(0)}$ and, further, an estimate of the subsampled channel coefficients $H_{m,i}^{q}$ according to (7). Finally, inverting (6) to obtain estimated DFT coefficients $\hat{F}_{m,i}^{q}$ and using $\hat{F}_{m,i}^{q}(0)$ as estimates of all $R_{m,i}$.

For the remaining blocks, we use a MOD-CS recovery algorithm in a sequential (recursive) manner. Suppose we already calculated an estimate $\hat{x}^{(q)}$ of $x^{(q)}$ for some $q \in \{0, \ldots, Q-2\}$. Then, we obtain an estimate $\hat{x}^{(q+1)}$ of $x^{(q+1)}$ by means of MOD-BPDN or MOD-OMP, using for the prior support $R^{(q)}$ that part of the support of $\hat{x}^{(q)}$ that is expected to best match the support of $x^{(q)}$. Because we do not know $x^{(q+1)}$, we define $R^{(q)}$ as the set of the indices of the $|R^{(q)}|$ entries of $\hat{x}^{(q)}$ with largest magnitudes, for a prescribed cardinality $|R^{(q)}|$, or, alternatively, as the set of the indices of all entries of $\hat{x}^{(q)}$ whose magnitudes are above a prescribed threshold $\gamma > 0$. Then, we proceed similarly as explained further above for $x^{(0)}$: we scale the estimate $\hat{x}^{(q+1)}$ with $D^{(q+1)}$; calculate estimates of $H_{m,i}^{q+1}$ according to (7), invert (6) to obtain $\hat{F}_{m,i}^{q+1}$, and finally use (3) to get estimates of all $H_{m,i}^{q+1}$. We note that conventional compressive channel estimation is reobtained if $R^{(q)} = \emptyset$ for all $q = 0, \ldots, Q-2$.

For consistency with the standard construction of the measurement matrix $\Phi^{(q)}$ [16], the pilot positions $P^{(q)}$ are chosen uniformly at random from the subsampled grid $\mathcal{G}$. For $P^{(q)}$ sufficiently large, this implies desirable performance guarantees, cf. [2] and Section 3.

5. SEQUENTIAL DELAY-DOPPLER SPARSITY

In this section, extending our analysis in [2, 17], we study the "sequential sparsity" of the delay-Doppler channel coefficients $F_{m,i}^{q}$. We assume that for each symbol block $q \in \{0, \ldots, Q-1\}$, the channel comprises $P$ propagation paths corresponding to the same $P$ specular scatterers with $q$-dependent time delays $\tau^{(q)}_p$ and Doppler frequency shifts $\nu^{(q)}_p$ ($p = 1, \ldots, P$). We also assume that $\tau^{(q)}_p$ and $\nu^{(q)}_p$ remain constant over the duration $T_0$ of the $q$th symbol block ($T_0 \approx T, NL$). We note that these assumptions are only made for analyzing the sequential sparsity of the $F_{m,i}$; they are not needed for our channel tracking method. For this channel model, the impulse response for $t \in [qT_0, (q+1)T_0)$ can be written as

$$h^{(q)}(t, \tau) = \sum_{p=1}^{P} \eta_p \delta(t - \tau^{(q)}_p) e^{2\pi \nu^{(q)}_p t}$$

where $\eta_p$ characterizes the complex attenuation of the $p$th propagation path and $\delta(\cdot)$ is the Dirac delta. Because $\eta_p$ does not depend on $q$, paths are not allowed to vanish or reappear for different blocks. (However, small variations of $\eta_p$ with $q$ do not invalidate our analysis.) The spreading function for block $q$ (cf. (4)) then becomes [2]

$$S^{(q)}_B[m,i] = \sum_{p=1}^{P} \eta_p e^{2\pi \nu^{(q)}_p m - \frac{\pi}{\nu^{(q)}_p} \nu^{(q)}_p (N - L - 1)} \Lambda^{(q)}_{P}[m,i],$$

with the shifted leakage kernels

$$\Lambda^{(q)}_{P}[m,i] = \phi^{(q)}_{P}(m - \tau^{(q)}_P/T, \psi(i - \nu^{(q)}_P T, NL)),$$

where $\phi^{(q)}_{P}(x) = \int_{-\infty}^{\infty} e^{-2\pi \nu x} f_1(T_0 x - t) f_2(t) dt$ and $\psi(x) = \sin(\pi x)/[NL \sin(\pi x/NL)]$. The $p$th leakage kernel $\Lambda^{(q)}_{P}[m,i]$ is effectively supported in a rectangular region of size $\Delta_m \times \Delta_\nu$, with some $\Delta_m$ and $\Delta_\nu$, that is centered about the delay-Doppler point $\xi^{(q)}_P = (\tau^{(q)}_P/T, \nu^{(q)}_P T, NL)$ [2]. Therefore, each $\Lambda^{(q)}_{P}[m,i]$ can be considered approximately $S_A$-sparse, where $S_A = \Delta_m \Delta_\nu$.

For a given block $q$, let $w^{(q)}_{P}$ be the vector connecting a given scatterer $p$ with the transmitter, and $w_{K,p}$ the vector connecting that scatterer with the receiver. Furthermore, let $v^{(q)}_{P}$ and $v^{(q)}_{K}$ be the velocity vectors of, respectively, the transmitter and the receiver relative to scatterer $p$, and let $u^{(q)}_{P} = \Lambda^{(q)}_{P}[w_{P}^{(q)}]$ and $u^{(q)}_{K} = \Lambda^{(q)}_{K}[w_{K}^{(q)}]$, where $c$ is the speed of light, and the Doppler shift for scatterer $p$ is $\nu^{(q)}_P = \frac{\nu}{c} (v^{(q)}_{P}T_{r,p} + v^{(q)}_{K}T_{s,p})$, where $T_{r,p}$ denotes the carrier frequency.

For two consecutive blocks $q$ and $q+1$, we have $w^{(q+1)}_{P} \approx w^{(q)}_{P} + T_0 v^{(q+1)}_{T}$ and $w^{(q+1)}_{K} \approx w^{(q)}_{K} + T_0 v^{(q+1)}_{S}$. Therefore, the time delay shift difference $\Delta^{(q)}_{P} \approx \| \tau^{(q+1)}_P - \tau^{(q)}_P \|$ can be (approximately) bounded as $\Delta^{(q)}_{P} \leq \tau^{(q)}_P$, with

$$\tau^{(q)}_P = \frac{T_0 (v^{(q)}_{T} + v^{(q)}_{S})}{c}.$$

Moreover, using the triangle and Cauchy-Schwarz inequalities, the Doppler shift difference $\Delta^{(q)}_{P} \approx \| \nu^{(q+1)} - \nu^{(q)} \|$ can be shown to satisfy $\Delta^{(q)}_{P} \leq \tau^{(q)}_P$, with

$$\tau^{(q)}_P = \frac{f_2}{\nu} \left( \Delta^{(q)}_{1,T} + 2v^{(q+1)}_{T} \Delta u^{(q)}_{K} \right) + \Delta u^{(q)}_{K} + 2v^{(q+1)}_{T} \Delta u^{(q)}_{K},$$

where $\Delta u^{(q)}_{K} = \| u^{(q+1)}_{K} - u^{(q)}_{K} \|_2$, $\Delta u^{(q)}_{1,T} = \| u^{(q+1)}_{K} - u^{(q)}_{K} \|_2$, $\Delta u^{(q)}_{K} = \| w^{(q+1)}_{K} - w^{(q)}_{K} \|_2$, $\Delta u^{(q)}_{1,T} = \| w^{(q+1)}_{K} - w^{(q)}_{K} \|_2 \approx T_0 v^{(q)}_{S}$.

We now recall that the leakage kernel for path $p$, $\Lambda^{(q)}_{P}[m,i]$, is centered about the delay-Doppler point $\xi^{(q)}_P = (\tau^{(q)}_P/T, \nu^{(q)}_P T, NL)$. The above bounds on $\Delta^{(q)}_{P}$ and $\Delta^{(q)}_{P}$ show that the center points $\xi^{(q)}_P$ and $\xi^{(q+1)}_P$ of the leakage kernels for two consecutive blocks $q$ and $q+1$ differ at most by $\Delta m^{(q)}_{P}$ in the $m$ direction and by $\Delta I^{(q)}_P \approx \| \nu^{(q+1)}_P, v^{(q)}_{P} T, NL \|$ in the $i$ direction. For practical velocities $v^{(q)}_{P}$ and $v^{(q)}_S$ and parameters $N$ and $L$, it follows from (11) with $T_0 \approx T, NL$ that $\Delta m^{(q)}_{P}$ will be small. Furthermore, if
the velocities do not change too quickly, i.e., if $\Delta v_i^{(q)}$ and $\Delta v_k^{(q)}$ are small, and if the relative distance variations $\Delta w_j^{(q)}/w_j^{(q)}$ and $\Delta w_k^{(q)}/w_k^{(q)}$ are not too large (this is typically true in practice), it follows from (12) that $\Delta v_i^{(q)}$ will be small. Therefore, the supports of $S_i^{(q)}(m,i)$ and $S_{i+1}^{(q)}(m,i)$, and consequently (see (10)) of $S_i^{(q)}(m,i)$ and $S_{i+1}^{(q)}(m,i)$, have a large overlap. This demonstrates the sequential delay-Doppler sparsity of practical channels and justifies the basic rationale underlying our compressive channel tracking method.

6. SIMULATION RESULTS

We simulated a CP-OFDM system with $K = 512$ subcarriers, CP length $N-K = 128$, QPSK symbols, carrier frequency $f_c = 5$ GHz, and bandwidth $B = 1/T_c = 5$ MHz. The system employed Gray labeling, a rate-1/2 convolutional code, and $32 \times 16$ row-column interleaving. The interpolation/anti-aliasing filters were root-raised-cosine filters with roll-off factor 1/4.

We used the channel simulation tool lInProp [18] to generate a doubly selective channel during $Q = 10$ blocks of $L = 32$ OFDM symbols each. For each simulation run, the transmitter and receiver were separated by approximately 1500 m, and 7 clusters of 10 specular scatterers each were randomly distributed between them. Of these, 3 clusters surrounded the receiver within a distance of up to 100 m. Scatterers and receiver were assigned random velocity and acceleration vectors with uniformly distributed directions, velocities of up to 50 m/s, and accelerations of up to 7 m/s$^2$.

The discrete version of the noise $z(t)$ in (1) was complex white Gaussian, with its variance $\sigma_z^2$ adjusted to achieve a prescribed receive signal-to-noise ratio (SNR). The SNR is defined as the mean receive signal power averaged over one block of length $NL$, divided by $\sigma_z^2$. The pilot set was identical for all OFDM blocks, i.e., $\mathcal{P}(q) \equiv \mathcal{P}$, and chosen randomly from the subsampled grid $\mathcal{G}$ (the grid spacings were $\Delta L = 1$ and $\Delta K = 4$). We used $|\mathcal{P}| = 1024$ pilots, corresponding to 6.25% of all symbols.

We compared our channel tracking method using MOD-OMP with conventional compressive channel estimation using OMP [2]. For both methods, the 2D DFT basis and an optimized basis (designed as in [2]) were used. For MOD-OMP, $\mathcal{R}^{(q)}$ was chosen as the 95% of the support of $\hat{x}^{(q)}$ corresponding to the largest-magnitude entries of $\hat{x}^{(q)}$. In Fig. 1, we show the normalized mean-square error (MSE) of channel tracking/estimation and the bit error rate (BER) as a function of the SNR. It can be seen that compressive channel tracking outperforms conventional compressive channel estimation both for the 2D DFT basis and for the optimized basis. Additionally, since $|\mathcal{R}^{(q)}|$ is quite large, the computational complexity is reduced substantially.

7. CONCLUSION

Based on the recently introduced concept of modified compressed sensing, we extended the computational efficiency of doubly selective channels to a sequential tracking operation where channel estimates are recursively updated. Our compressive channel tracker uses a modified version of the OMP recovery algorithm that exploits partial support information and has a lower complexity than the classic OMP algorithm. Simulation results demonstrated substantial performance gains over conventional compressive channel estimation.
