Abstract—Cellular systems that employ time division duplexing (TDD) transmission are good candidates for implementation of interference alignment (IA) in the downlink since channel reciprocity enables the estimation of the channel state by the base stations (BS) in the uplink phase. However, the interfering BSs need to share their channel estimates via backhaul links of finite capacity. A quantization scheme is proposed which reduces the amount of information exchange (compared to conventional methods) required to achieve IA in such a system. The scaling (with the transmit power) of the number of bits to be exchanged between the BSs that is sufficient to preserve the multiplexing gain of IA is derived.¹

I. INTRODUCTION

Interference alignment (IA) is known to achieve the optimal degree of freedom (DoF) in the interference channel (IC). This implies that at high signal to noise ratio (SNR) regime, IA improves the system throughput compared to the conventional orthogonal medium-sharing methods. However, implementation of IA in existing systems faces a lot of challenges. The necessity of channel state information (CSI) at the transmitters is one of the major issues which is not practical in many situations. Moreover, the accuracy of the CSI provided to the transmitters should increase as the SNR increases in order to guarantee the DoF gains promised by IA [1]. Therefore transmission systems which acquire the CSI through feedback (such as frequency division duplex (FDD) systems) become less favorable for implementation of IA since the potential gains only appear at high powers.

For time division duplex (TDD) systems, every base station can estimate its downlink channels from the uplink transmission phase thanks to reciprocity. If IA precoders are designed at the transmitter side (no interaction with the receiver side) then the BSs need to share their channel estimates which can be carried out through backhaul links between BSs. These backhaul links generally have limited capacity, which should be exploited efficiently.

In scenarios where the receivers quantize and feed the CSI back to the transmitters, the problem is explored over frequency selective channels for single-antenna users in [1] and for multiple-antenna users in [2]. Both references provide DoF-achieving quantization schemes and establish the required

scaling of the number of feedback bits. For alignment using spatial dimensions, [3] provides the scaling of feedback bits to achieve IA in MIMO IC. For the broadcast channel, the scaling of the feedback bits was characterized in [4]. In [5], quantization of the precoding matrix using random vector quantization (RVQ) codebooks is investigated which provides insights on the asymptotic optimality of RVQ. From another point of view, [6] provides an analysis of the effect of imperfect CSI on the mutual information of the interference alignment scheme.

In this paper, we focus on the scenario where the BSs have perfect but local CSI, and must share it to achieve IA. A CSIT sharing scheme is proposed which reduces the amount of information exchange required for interference alignment in such a system. The scaling (with the transmit power) of the number of bits to be transferred which is sufficient to preserve the multiplexing gain that can be achieved using perfect CSI is derived. Moreover, a heuristic method is proposed to demonstrate the achievability of the DoF by simulations.

Notation: Boldface lowercase and uppercase letters indicate vectors and matrices, respectively. \mathbf{I}_N is the $N \times N$ identity matrix. The trace, conjugate, Hermitian transpose of a matrix or vector are denoted by $\text{tr}(\cdot)$, $(\cdot)^*$, $(\cdot)^H$ respectively. The expectation operator is represented by $E(\cdot)$. The Frobenius norm and the determinant of a matrix are denoted by $\|\cdot\|_F$ and $|\cdot|$ respectively. The maximum eigenvalue of a matrix is represented by $\lambda_{\max}(\cdot)$. A diagonal (resp. block diagonal) matrix is denoted by $\text{diag}(\cdot)$ (resp. $\text{Bdiag}(\cdot)$) with the argument elements (resp. blocks) on its diagonal. $\mathcal{N}(0, 1)$ (resp. $\mathcal{CN}(0, 1)$) denotes the real (resp. circularly symmetric complex) Gaussian distribution with zero mean and unit variance.

II. SYSTEM MODEL

An interference channel is considered in which K base stations (BS) and K users (one user in each cell) are considered as transmitters and receivers, respectively. For the sake of simplicity of the exposition, we focus on the symmetric case, and assume that each BS has M antennas while each user is equipped with N antennas. These results trivially generalize to non-homogeneous antenna numbers and per-user DoF as long as IA is feasible for the chosen problem dimensions. Each BS employs a linear precoder to transmit d data streams to its

user. The received signal at user i is denoted by

$$\mathbf{y}_i = \mathbf{H}_{ii} \mathbf{V}_i \mathbf{x}_i + \sum_{j=1, j \neq i}^K \mathbf{H}_{ij} \mathbf{V}_j \mathbf{x}_j + \mathbf{n}_i \quad (1)$$

in which $\mathbf{H}_{ij} \in \mathbb{C}^{N \times M}$ is the channel matrix between BS j and user i , $\mathbf{V}_j \in \mathbb{C}^{M \times d}$ and $\mathbf{x}_j \in \mathbb{C}^d$ are the precoding matrix and the data vector of BS j , respectively. Furthermore, \mathbf{n}_i is the additive noise at user i whose entries are distributed according to $\mathcal{CN}(0, 1)$. Assuming $E(\mathbf{x}_j \mathbf{x}_j^H) = \frac{P}{d} \mathbf{I}_d$, $j = 1, \dots, K$ and using truncated unitary precoders, the transmit power for each BS is equal to P . We further assume that the elements of the data symbol are i.i.d. Gaussian random variables. The channels are assumed to be generic [7]; in particular, this includes channels with entries drawn independently from a continuous distribution.

III. CSIT SHARING FOR IA

Let us consider TDD transmission, which enables the BSs to estimate their channels toward different users by exploiting the reciprocity of the wireless channel. Specifically, we assume that the j th BS estimates the channel matrices \mathbf{H}_{ij} , $i = 1, \dots, K$, $i \neq j$ (denoted by *local CSI*) from the uplink phase, via reciprocity. We first assume that local CSI is known perfectly at BS j . However, global CSI (excluding the direct channels \mathbf{H}_{ii}) is required in order to design IA precoders. In this section we consider the topology of CSI exchange in the network, and work under the assumption that perfect local CSI is conveyed from each BS to a processing node which computes all precoders and provides them to the BSs.

Here we assume a feasible IA setting [8], i.e. there exist precoding matrices \mathbf{V}_j , $j = 1, \dots, K$ and projection matrices $\mathbf{U}_i \in \mathbb{C}^{N \times d}$, $i = 1, \dots, K$ such that

$$\mathbf{U}_i^H \mathbf{H}_{ij} \mathbf{V}_j = \mathbf{0} \quad \forall i, j \in \{1, \dots, K\}, j \neq i, \quad (2)$$

$$\text{rank}(\mathbf{U}_i^H \mathbf{H}_{ii} \mathbf{V}_i) = d. \quad (3)$$

Condition (2) can be rewritten as

$$\mathbf{U}_{-j}^H \mathbf{H}_j \mathbf{V}_j = \mathbf{0} \quad \forall j \in \{1, \dots, K\}, \quad (4)$$

in which $\mathbf{U}_{-j} = \text{Bdiag}(\mathbf{U}_1, \dots, \mathbf{U}_{j-1}, \mathbf{U}_{j+1}, \dots, \mathbf{U}_K)$ and $\mathbf{H}_j = [\mathbf{H}_{1,j}^H, \dots, \mathbf{H}_{j-1,j}^H, \mathbf{H}_{j+1,j}^H, \dots, \mathbf{H}_{K,j}^H]^H$ is a $(K-1)N \times M$ matrix.

We will further assume that $(K-1)N > M$, which represents the cases where transmitter-side zero-forcing is not enough to eliminate all interference, and therefore IA is required. The following lemma highlights the intuition behind our CSI sharing scheme.

Lemma 1: In order to design IA precoders, it is sufficient that each BS j sends a point on the Grassmann manifold $\mathcal{G}_{(K-1)N, M}$ representing the column space of \mathbf{H}_j to the IA processing node.

Proof: Let \mathbf{F}_j denote a $(K-1)N \times M$ matrix containing an orthonormal basis of the column space of \mathbf{H}_j , i.e. $\mathbf{H}_j = \mathbf{F}_j \mathbf{C}_j$ for some \mathbf{C}_j (invertible almost surely for generic channels). According to our assumption that only the

column space of \mathbf{H}_i is known at the central unit, we can assume that the central unit has only access to a rotated version of \mathbf{F}_j , i.e., $\mathbf{F}_j \mathbf{O}_j$ for some unknown unitary matrix \mathbf{O}_j . We now show that alignment can be achieved based on the knowledge of $\mathbf{F}_j \mathbf{O}_j$ rather than of \mathbf{H}_j . Let us assume that the processing node designs a set $(\{\tilde{\mathbf{U}}_j\}_{j=1}^K, \{\tilde{\mathbf{V}}_j\}_{j=1}^K)$ of IA transmit precoders and receive projection filters for the channels $\{\mathbf{F}_j \mathbf{O}_j\}_{j=1}^K$. Then,

$$\tilde{\mathbf{U}}_{-j}^H (\mathbf{F}_j \mathbf{O}_j) \tilde{\mathbf{V}}_j = \mathbf{0} \Rightarrow \tilde{\mathbf{U}}_{-j}^H \mathbf{F}_j \mathbf{C}_j \mathbf{C}_j^{-1} \mathbf{O}_j \tilde{\mathbf{V}}_j = \mathbf{0} \quad (5)$$

$$\Rightarrow \tilde{\mathbf{U}}_{-j}^H \mathbf{H}_j \mathbf{C}_j^{-1} \mathbf{O}_j \tilde{\mathbf{V}}_j = \mathbf{0}. \quad (6)$$

This indicates that IA is achieved over the real channel by using $\mathbf{C}_j^{-1} \mathbf{O}_j \tilde{\mathbf{V}}_j$ as precoder and $\tilde{\mathbf{U}}_j$ as the projection filter at user j . Assuming that $\tilde{\mathbf{V}}_j$ is transmitted from the processing node back to BS j , and that \mathbf{O}_j is known at BS j since the reconstruction codebook of the processing node is known, the BS is in a position to compute the precoder $\mathbf{C}_j^{-1} \mathbf{O}_j \tilde{\mathbf{V}}_j$. ■

Note that the feedback of $\tilde{\mathbf{V}}_j$ from the processing node to BS j also takes the form of a point on $\mathcal{G}_{M, d}$, and will be analyzed in further detail in the sequel.

IV. CSIT SHARING OVER FINITE CAPACITY LINKS

In this section, using the Grassmannian representation outlined in the previous section, we explore several scenarios where CSI is quantized and exchanged between the nodes over finite capacity links. Three different scenarios regarding the CSIT sharing problem can be considered:

- I. The IA processing node is a separate central node that computes and distributes the IA precoders to the K BSs,
- II. One BS also acts as the IA processing node,
- III. Each BS receives all the required CSI and independently computes the IA precoders.

In scenario I (Fig. 1(a)), the CSI (in the form of \mathbf{F}_j) is quantized yielding $\hat{\mathbf{F}}_j$ and sent to the central node. The central node computes the precoders and provides BS j a quantized version $\hat{\mathbf{V}}_j$ of $\tilde{\mathbf{V}}_j$. Here we assume that each BS uses N_b bits to quantize \mathbf{F}_j and the central node uses N_c bits to quantize $\tilde{\mathbf{V}}_j$. Therefore, the total number of bits exchanged over the network for scenario I is equal to $K(N_b + N_c)$. Scenario II can be considered as a particular example of scenario I where one (bi-directional) BS-central node link is saved; the number of bits to be transferred in the network is $(K-1)(N_b + N_c)$. In scenario III (Fig. 1(b)), the IA solution is computed independently at each BS, requiring global CSI at each BS. Therefore each BS needs to quantize and send its local CSI to all other $K-1$ BSs. The precoders are designed at the BSs and no further information exchange is required. For simplicity of the exposition, we focus on scenario I and characterize the scaling of N_b and N_c with P , noting that a generalization of the analysis to scenarios II and III is straightforward.

Let us first consider the feedback from a BS to the central node. BS j performs the QR decomposition $\mathbf{H}_j = \mathbf{F}_j \mathbf{C}_j$ and quantizes the subspace spanned by the columns of \mathbf{F}_j

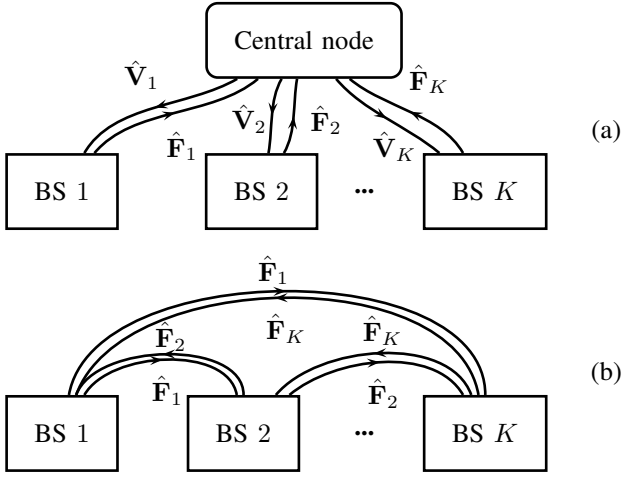

Fig. 1. CSIT sharing, with (a) and without (b) central node.

using N_b bits and sends the index of the quantized codeword to the central node. We further assume that the BSs and the central node share a predefined codebook $\mathcal{S} = \{\mathbf{S}_1, \dots, \mathbf{S}_{2^{N_b}}\}$ which is composed of 2^{N_b} truncated unitary matrices of size $(K-1)N \times M$ and is designed using Grassmannian subspace packing. For simplicity, let us assume that all K codebooks have the same size and the powers of the transmitted signals and receiver noise are symmetric across the network. The quantized codeword is the closest point in \mathcal{S} w.r.t. the chordal distance, i.e.,

$$\hat{\mathbf{F}}_j = \arg \min_{\mathbf{S} \in \mathcal{S}} d_c(\mathbf{S}, \mathbf{F}_j) \quad (7)$$

in which $d_c(\mathbf{X}, \mathbf{Y}) = \frac{1}{\sqrt{2}} \|\mathbf{X}\mathbf{X}^H - \mathbf{Y}\mathbf{Y}^H\|_{\text{F}}$ is the chordal distance between two points in $\mathcal{G}_{(K-1)N, M}$ represented by truncated unitary matrices \mathbf{X} and \mathbf{Y} [9]. The interference alignment problem is then solved at the central node based on $\{\hat{\mathbf{F}}_j\}_{j=1}^K$ to find $(\{\tilde{\mathbf{U}}_j\}_{j=1}^K, \{\tilde{\mathbf{V}}_j\}_{j=1}^K)$ fulfilling

$$\tilde{\mathbf{U}}_j^H \hat{\mathbf{F}}_j \tilde{\mathbf{V}}_j = \mathbf{0}, \quad \forall j \in \{1, \dots, K\}. \quad (8)$$

We now consider the feedback of $\tilde{\mathbf{V}}_j$ from the central node to BS j . Using another codebook $\mathcal{T} = \{\mathbf{T}_1, \dots, \mathbf{T}_{2^{N_c}}\}$ of truncated unitary matrices representing points in $\mathcal{G}_{M, d}$, the central node quantizes the alignment precoder $\tilde{\mathbf{V}}_j$ for each BS on $\mathcal{G}_{M, d}$ according to

$$\hat{\mathbf{V}}_j = \arg \min_{\mathbf{T} \in \mathcal{T}} d_c(\mathbf{T}, \tilde{\mathbf{V}}_j), \quad (9)$$

and sends the corresponding index to BS j . At BS j , we define the total precoder as $\mathbf{V}_j = \mathbf{C}_j^{-1} \mathbf{F}_j^H \hat{\mathbf{F}}_j \hat{\mathbf{V}}_j$, by analogy to the perfect CSI case (Lemma 1). Using the precoders \mathbf{V}_j and after applying the receive filter $\tilde{\mathbf{U}}_i$ to (1), the interference leakage (due to the quantizations (7) and (9)) at user i is defined as

$$\mathbf{e}_i = \sum_{\substack{1 \leq j \leq K \\ j \neq i}} \tilde{\mathbf{U}}_i^H \mathbf{H}_{ij} \mathbf{V}_j \mathbf{x}_j. \quad (10)$$

We denote the leakage power at user i by $L_i = \text{tr}(\mathbf{E}(\mathbf{e}_i \mathbf{e}_i^H)) = \text{tr}(\frac{P}{d} \mathbf{Q}_I^i)$, where $\mathbf{Q}_I^i = \sum_{j=1, j \neq i}^K \tilde{\mathbf{U}}_i^H \mathbf{H}_{ij} \mathbf{V}_j \mathbf{V}_j^H \mathbf{H}_{ij}^H \tilde{\mathbf{U}}_i$. We

now consider the sum over all users of the leakage powers:

$$\begin{aligned} L &= \sum_{i=1}^K \text{tr} \left(\frac{P}{d} \sum_{j=1, j \neq i}^K \tilde{\mathbf{U}}_i^H \mathbf{H}_{ij} \mathbf{V}_j \mathbf{V}_j^H \mathbf{H}_{ij}^H \tilde{\mathbf{U}}_i \right) \\ &= \sum_{j=1}^K \frac{P}{d} \|\tilde{\mathbf{U}}_{-j}^H \mathbf{H}_j \mathbf{V}_j\|_{\text{F}}^2. \end{aligned} \quad (11)$$

Substituting $\mathbf{V}_j = \mathbf{C}_j^{-1} \mathbf{F}_j^H \hat{\mathbf{F}}_j \hat{\mathbf{V}}_j$ and $\mathbf{H}_j = \mathbf{F}_j \mathbf{C}_j$ gives

$$\|\tilde{\mathbf{U}}_{-j}^H \mathbf{H}_j \mathbf{V}_j\|_{\text{F}}^2 = \|\tilde{\mathbf{U}}_{-j}^H \mathbf{F}_j \mathbf{F}_j^H \hat{\mathbf{F}}_j \hat{\mathbf{V}}_j\|_{\text{F}}^2. \quad (12)$$

From (8) we have $\tilde{\mathbf{U}}_{-j}^H \hat{\mathbf{F}}_j \tilde{\mathbf{V}}_j \tilde{\mathbf{V}}_j^H \hat{\mathbf{V}}_j = \mathbf{0}$, therefore by some manipulations, from (11), (12) we get

$$L = \sum_{j=1}^K \frac{P}{d} \|\mathbf{X}_j^b + \mathbf{X}_j^c\|_{\text{F}}^2 \leq \sum_{j=1}^K \frac{P}{d} (\|\mathbf{X}_j^b\|_{\text{F}} + \|\mathbf{X}_j^c\|_{\text{F}})^2 \quad (13)$$

where

$$\begin{aligned} \mathbf{X}_j^b &= \tilde{\mathbf{U}}_{-j}^H (\mathbf{F}_j \mathbf{F}_j^H - \hat{\mathbf{F}}_j \hat{\mathbf{F}}_j^H) \hat{\mathbf{F}}_j \hat{\mathbf{V}}_j \quad \text{and} \\ \mathbf{X}_j^c &= \tilde{\mathbf{U}}_{-j}^H \hat{\mathbf{F}}_j (\hat{\mathbf{V}}_j \hat{\mathbf{V}}_j^H - \tilde{\mathbf{V}}_j \tilde{\mathbf{V}}_j^H) \hat{\mathbf{V}}_j. \end{aligned} \quad (14)$$

Using the fact that all the matrices involved in \mathbf{X}_j^b and \mathbf{X}_j^c are truncated unitary, it can be shown that $\|\mathbf{X}_j^b\|_{\text{F}} \leq \sqrt{2d} d_c(\mathbf{F}_j, \hat{\mathbf{F}}_j)$ and $\|\mathbf{X}_j^c\|_{\text{F}} \leq \sqrt{2d} d_c(\hat{\mathbf{V}}_j, \tilde{\mathbf{V}}_j)$. Using bounds on the quantization error for codebooks designed by sphere packing, it can be shown [3] that L in (13) is upper bounded by a constant c_0 independent of P when

$$N_b = \frac{G_b}{2} \log P \quad \text{and} \quad N_c = \frac{G_c}{2} \log P, \quad (15)$$

in which $G_b = 2M((K-1)N - M)$ and $G_c = 2d(M - d)$ are the real dimension of $\mathcal{G}_{(K-1)N, M}$ and $\mathcal{G}_{M, d}$ respectively. Under the conditions (15), it is clear that the leakage power at every receiver would be bounded by a constant since $L_i \leq L$.

In order to establish the DoF achievable using the proposed CSI quantization scheme, we provide a lower bound for the achievable rate. First consider the following lemma:

Lemma 2: For N_b and N_c according to (15) we have,

$$\lim_{P \rightarrow \infty} \frac{\log |\mathbf{I}_d + \frac{P}{d} \mathbf{Q}_S^i|}{\log P} = d, \quad (16)$$

with $\mathbf{Q}_S^i = \mathbf{U}_i^H \mathbf{H}_{ii} \mathbf{V}_i \mathbf{V}_i^H \mathbf{H}_{ii}^H \mathbf{U}_i$, almost surely.

Proof: Note that the limit in (16) involves codebooks of increasing size since N_b and N_c increase with P . \mathbf{Q}_S^i does not necessarily admit a limit when $P \rightarrow \infty$ due to the fact that \mathbf{U}_i and \mathbf{V}_i are functions of the codebook. We tackle this problem by resorting to an argument based on the compactness of the solution space, and show that there exists a series of codebooks of increasing size for which \mathbf{Q}_S^i admits a limit and is full rank a.s. The full proof is similar to the proof of Theorem 2 in [10], and is omitted due to space constraints. ■

We are now in the position of proving that the proposed method achieves the full IA DoF:

Theorem 1: The proposed quantization scheme, with N_b and N_c according to (15), achieves the same DoF as IA under perfect CSI.

Proof: Recall that (15) ensures that $L_i \leq c_0$. Therefore, $\lambda_{\max} \left(\frac{P}{d} \mathbf{Q}_I^i \right) \leq \text{tr} \left(\frac{P}{d} \mathbf{Q}_I^i \right) = L_i \leq c_0$, which yields

$$\log \left| \mathbf{I}_d + \frac{P}{d} \mathbf{Q}_I^i \right| \leq d \log \left(1 + \lambda_{\max} \left(\frac{P}{d} \mathbf{Q}_I^i \right) \right) \leq d \log(1 + c_0). \quad (17)$$

Hence, the achievable rate using the designed precoders and receive filters denoted by R_q^i for user i can be lower-bounded as follows,

$$R_q^i = \log \left| \mathbf{I}_d + \frac{P}{d} (\mathbf{Q}_S^i + \mathbf{Q}_I^i) \right| - \log \left| \mathbf{I}_d + \frac{P}{d} \mathbf{Q}_I^i \right| \quad (18)$$

$$\geq \log \left| \mathbf{I}_d + \frac{P}{d} \mathbf{Q}_S^i \right| - \log \left| \mathbf{I}_d + \frac{P}{d} \mathbf{Q}_I^i \right| \quad (19)$$

$$\geq \log \left| \mathbf{I}_d + \frac{P}{d} \mathbf{Q}_S^i \right| - d \log(1 + c_0), \quad (20)$$

where (19) follows from the fact that \mathbf{Q}_I^i is positive semi-definite and the second inequality follows from (17). Combining (20) with Lemma 2 brings us to the conclusion that $\lim_{P \rightarrow \infty} \frac{R_q^i}{\log P} \geq d$, i.e. the full DoF are achieved. ■

V. SIMULATION RESULTS AND DISCUSSION

A. Performance results using RVQ

In this section, the performance of the proposed scheme is evaluated through numerical simulations. The performance metric is the sum-rate evaluated through Monte-Carlo simulations employing truncated unitary precoders. A three-user IC is considered where each BS is equipped with $M = 5$ antennas while every receiver has $N = 3$ antennas and $d = 2$ data streams for each user is considered. Entries of the channel matrices are generated according to $\mathcal{CN}(0, 1)$ and the performance results are averaged over the channel realizations. In Fig. 2, the quantized CSI feedback method of Section IV (denoted by ‘‘Proposed’’) is compared (for scenario I) to the naive method where the interfering channel matrices from the BSs are independently vectorized, normalized and quantized using N_b bits based on the idea of composite Grassmann manifold [2] and finally the indices of the quantized vectors are sent to the central node (denoted by Normalized Channel Composite Grassmann Quantization, NC-CGQ). At the central node, for the proposed method, the precoders are quantized on $\mathcal{G}_{M,d}$ while for the NC-CGQ method, each precoder is vectorized, normalized and quantized on $\mathcal{G}_{M,d,1}$ using N_c bits, and sent to the corresponding BS. Figure 2 shows the achievable sum-rate versus transmit SNR (P) for $(N_b, N_c) = (5, 6)$ and $(N_b, N_c) = (10, 12)$ bits. A random codebook is used with codebook entries chosen as independent truncated unitary matrices generated from the Haar distribution. For the independent quantization method, random unit norm vectors are used in the codebook construction. Clearly the proposed scheme outperforms the independent quantization method for the same number of bits.

Fig. 2. Sum-rate comparison of quantization methods, for the 3-user MIMO IC, $M = 5$, $N = 3$, $d = 2$, based on optimal decoding of \mathbf{y}_i .

B. Perturbations on the Grassmann manifold

The use of random codebooks for large values of N_b and N_c is not tractable, due to the exponential requirements in terms of storage and of computation of (7) and (9). In order to benchmark the sum-rate achievable under the proposed scheme for the high power region (large N_b and N_c) we replace the quantization process with a perturbation which approximates the quantization error. As will be seen, this approach provides a good approximation of the effect of quantization on the considered system. We now detail the proposed perturbation technique.

Let us consider a point on $\mathcal{G}_{n,p}$, represented by a $n \times p$ truncated unitary matrix \mathbf{F} . Here, we assume that $n \geq 2p$, since it is otherwise more efficient to consider the left null space of \mathbf{F} instead. Since the columns of \mathbf{F} are orthonormal, they can be completed to form an orthonormal basis of the n -dimensional space. In fact, according to [11], any other point on $\mathcal{G}_{n,p}$ can be represented in the basis constituted by the columns of the unitary matrix $\mathbf{W} = [\mathbf{F} \mathbf{F}^c]$ as

$$\bar{\mathbf{F}} = \mathbf{W} \begin{bmatrix} \mathbf{C} \\ \mathbf{S} \\ \mathbf{0}_{n-2p} \end{bmatrix}, \quad (21)$$

for some \mathbf{F}^c in the left null space of \mathbf{F} and

$$\mathbf{C} = \text{diag}(\cos \theta_1, \dots, \cos \theta_p), \mathbf{S} = \text{diag}(\sin \theta_1, \dots, \sin \theta_p),$$

where $\theta_1, \dots, \theta_p$ are real angles. The squared chordal distance between the two points on $\mathcal{G}_{n,p}$ represented by \mathbf{F} and $\bar{\mathbf{F}}$ is $r \triangleq d_c^2(\mathbf{F}, \bar{\mathbf{F}}) = \sum_{i=1}^p \sin^2 \theta_i$. Therefore, in order to generate random perturbations of a certain chordal distance $\sqrt{r_0}$ from \mathbf{F} , we propose to generate random values for the angles $\theta_1, \dots, \theta_p$ such that $\sum_{i=1}^p \sin^2 \theta_i = r_0$, and to pick a random orthonormal basis \mathbf{F}^c of the left null subspace of \mathbf{F} . The perturbed matrix is then computed using (21). The histogram (not shown) of the squared quantization error obtained from

an RVQ implementation suggests that the Gaussian distribution is a good approximation for the probability density function of r . In fact, the moments of this distribution can be obtained using the following result from [9, Theorem 6]: for asymptotically large codebook size, when using a random codebook \mathcal{C} of size J for quantizing a matrix \mathbf{F} arbitrarily distributed over an arbitrary manifold, the k -th moment of the quantization error distribution, $D^{(k)} = E_{\mathcal{C}, \mathbf{F}}(d_c^k(\hat{\mathbf{F}}, \mathbf{F}))$ for $\hat{\mathbf{F}} = \arg \min_{\mathbf{C} \in \mathcal{C}} d_c(\mathbf{F}, \mathbf{C})$, can be bounded as

$$\frac{G}{(G+k)(cJ)^{\frac{k}{\sigma}}} \leq D^{(k)} \leq \frac{\Gamma(\frac{k}{\sigma})}{\frac{G}{k}(cJ)^{\frac{k}{\sigma}}}, \quad (22)$$

where c and G are respectively the coefficient of the ball volume and the real dimension of the corresponding manifold (here, the Grassmann manifold). Note that (22) only provides bounds on $D^{(k)}$, however since both the upper and lower bounds are asymptotically tight when the codebook size increases, we arbitrarily choose to use the upper bound as an approximation of $D^{(k)}$, i.e.

$$\bar{r} \triangleq \frac{\Gamma(\frac{2}{\sigma})}{\frac{G}{2}(cJ)^{\frac{2}{\sigma}}} \approx D^{(2)} \quad (23)$$

is the average and

$$\sigma_r^2 \triangleq \frac{\Gamma(\frac{4}{\sigma})}{\frac{G}{4}(cJ)^{\frac{4}{\sigma}}} - \bar{r}^2 \approx D^{(4)} - (D^{(2)})^2 \quad (24)$$

is the variance. We propose generate the values for r according to $\mathcal{N}(\bar{r}, \sigma_r^2)$ truncated to \mathbb{R}^+ . This process is summarized in Algorithm 1.

Algorithm 1 Generating random perturbations around \mathbf{F}

- Draw a random realization of the squared chordal distance r from $\mathcal{N}(\bar{r}, \sigma_r^2)$
 - If $r < 0$ then generate a new sample
 - Generate independent s_1, \dots, s_p drawn uniformly from the interval $[0, 1]$
 - Compute the angles $\theta_i = \sin^{-1}\left(\frac{s_i \sqrt{r}}{\sqrt{\sum_{i=1}^p s_i^2}}\right)$
 - Generate a random orthonormal basis \mathbf{F}^c of the left null space of \mathbf{F} and compute $\hat{\mathbf{F}}$ according to (21).
-

This algorithm was used to simulate the effect of quantization taking place at BSs as well as the central node. The sum-rate performance $\sum_{i=1}^K R_q^i$ obtained using the perturbation method is plotted against SNR for various codebook sizes in Fig. 3. For the considered antenna configuration, according to (15), the scaling that is sufficient to achieve the perfect DoF is $N_b = 5 \log P$ and $N_c = 6 \log P$. In the simulations, the codebook sizes are chosen as $N_b = 5A$ and $N_c = 6A$ for integer values of A , and the corresponding SNR is computed according to $P = 2^A$. The results are also compared to perfect CSIT sharing. It is clear that this perturbation method effectively approximates the quantization process when the desired performance metric is the sum-rate, allowing us to rely on the curves resulting from this method to confirm the DoF result of Theorem 1.

Fig. 3. Sum rate comparison between perturbation method (dashed) and quantization (solid), for the 3-user MIMO IC, $M = 5$, $N = 3$ and $d = 2$, based on (18).

VI. CONCLUSION

A limited feedback scheme was proposed for efficient sharing of CSIT among interfering BSs in downlink interference alignment for TDD cellular systems. The growth rate of the bits to be transferred with respect to the transmit power was characterized in order to preserve the total multiplexing gain and a heuristic method was proposed to verify the achievability of the multiplexing gain by simulation.
