Preface: Programming is a drama.

ROMEO AND JULIET
by William Shakespeare

Juliet ........ Daughter to the Capulet Family
Romeo .... The Son of the Montague Clan

In a drama, it is normal to begin by introducing the audience to the cast of characters. Because programming is primarily a writing activity, the very same concept is used to give a sense of setting to a program:

ADDNUMBERS by John Doe
a....the first Number
b...the second Number
result ... the result of adding a and b

As in a play, the name of the program already hints at its content (or: purpose). Likewise, the names used in a program (here: a, b and result) should point at their role in the now beginning chain of events.

Introducing proper names may be difficult at start. It requires a clear concept of what a program should do and in which steps it is going arrive at its solution. Architects often find it difficult to concentrate on the problem their program should solve, when all they want is really “a fancy solution”. But understanding the problem, breaking it up into sub-problems which are easily solvable and finally arriving at the solution is what lies at the heart of programming. To teach both knowledge about programming as well as a basic understanding on how to model and structure problems is what we want to do within the lecture “Programming for Architects”. In this respect, we will often deviate from this pure “programmer’s handbook” and relate to how algorithms we present work, and how they can be understood.

Gabriel P.X. Wurzer and Wolfgang E. Lorenz
Vienna University of Technology

Introduction

Programming

Programming is more than writing a piece of software but a much broader activity for which we need the following components:

1. The brain, which comes up with the goal of a software (concept).
2. A text editor, in which the concept is translated into a sequence of instructions for a specific programming language (coding or implementation).
3. A program which checks our typed text for correctness and a.) executes our instructions immediately (interpretation) or generates an executable file (e.g. program.exe) which contains the instructions in machine-readable form (compilation).

Scripting versus programming

We differentiate between two main groups of programming languages:

1. A scripting language (e.g. Visual Basic for Applications or Python) is usually integrated into a particular application (e.g. Rhino, Cinema4D). It allows the programmer to access all of the application's features for adding new functionality in the form of a “self-written” program (script). Usually applications offering scripting support come with an inbuilt code editor in which scripts can be written and executed. The scripting language’s interpreter will then execute the code line by line, checking for correctness as it moves along.

2. A programming language differs insofar as that the program is written in a stand-alone text editor (called Integrated Development Environment, IDE) which calls up a compiler that translates all instructions into machine-readable form and writes out the result as an executable file (“.exe” file on Windows, “.so” or “.o” file on Linux, or a file with a special “executable” flag on a Mac). The program may then be run by clicking on the produced executable file (or have the IDE do so by clicking a “play” button).

A further difference between interpretation and compilation lies in the fact that compiled programs only run on the platform they were compiled for: An “.exe” file can only run on Windows and not on a Mac; one would need to additionally produce an executable file in Mac format for that. In contrast, code written in a scripting language runs everywhere as long as there is an interpreter - which is typically part of the hosting application (e.g. Cinema4D).

Another advantage of scripting is the possibility to use functionality of the hosting application within scripts (see e.g. the “record Macro” functionality in Microsoft Word which records all clicks and keypresses and produces a script containing application instructions). Compiled programs, on the other hand, do not offer any application-specific functionalities per default; for these to become available, one has to load a so-called library containing instructions for that specific application first.

Given the advantages of scripting languages, most architects stick to that form of coding. In our course, we will do likewise, using Rhino as our application and Python as scripting language.
A. **The stage: How to use Python in Rhino**

*[or what the stage looks like]*

A.1. **Programming language: Python**

Rhino provides several opportunities for extending the application, one of which is **Rhino.Python** (other are C/C#, Grasshopper, RhinoScript, RhinoCommon, openNURBS and RhinoMobile). Being a *scripting language*, Python executes code directly within the Rhino application. The benefit of this approach lies in the fact that no software except Rhino needs to be installed in order to be able to code. On the downside, however, one cannot write independent programs that are distributed without Rhino in this manner.

**Python** was developed by Guido van Rossum at Centrum Wiskunde & Informatica (CWI) in the Netherlands in the late 1980ies (implementation began in December 1989). It was developed as a successor to the ABC language. Major releases were Python 2.0 (released on October 16th, 2000) and Python 3.0 (released on December 3rd, 2008). For more detail see *Wikipedia: History of Python*.\(^1\)

*Python is a general-purpose interpreted, interactive, object-oriented, and high-level programming language.\(^2\)*

We decided to use Python because it is available in Rhino and comes with an editor that allows debugging. Originally we had chosen Visual Basic for Applications (VBA) for AutoCAD as scripting language, but decided to make a radical shift to Rhino/Python because of the following reasons:

1. In 2007, Microsoft (the company behind VBA) urged all application vendors to switch to their new .NET platform. The intention of Microsoft was no surprise, since VBA had been around for nearly 20 years and the company did not want to invest any more resources into a scripting platform not in its main strategy line. For some years VBA was still supported, however, the switch was unavoidable and would have meant some dramatic didactical changes (e.g. compilation instead of scripting).
2. Rhino (and Grasshopper) got increasingly popular among our students. In our digital design courses of the last couple of years we made the experience that the majority of them was already working with Grasshopper (not scripting per se but a dataflow language). Since programming (and hence this lecture) is not “only” about learning a programming language but also about the mental ability to formulate a program, switching to whatever language makes no difference once the basic programming constructs are understood.
3. The Python Editor is an integral part of the Rhino application. Code written in the Python Editor can be referred to and used in Grasshopper, which is the only additional plug-in we need (Rhino 6 already comes with Grasshopper, so even that isn’t needed).

---

\(^2\) [https://www.tutorialspoint.com/python/index.htm](https://www.tutorialspoint.com/python/index.htm) (02.03.2018). Interpreted means, that the script is executed line by line, which makes the flow more understandable.
A.2. Python for Rhino

We will write our code in Python for Rhino. Hence, Rhino is the only software you’ll need. A student license is available and costs around 195€ (excluding sales tax and shipment).\(^3\) Unlike other student versions, commercial use is allowed even after finishing your study. Rhino is also installed in the ARCH LAB of the TU Wien in case you have no computer at hand.\(^4\)

You can start the Python Editor by typing the command `EditPythonScript`. From there you can open Python files (.py), create new ones or edit existing ones.

### VBA for AutoCAD: References to VBA

Although the script is mainly about Rhino.Python we decided to mention cross connections to VBA, since we want to show differences in the syntax of another programming language as well. Those parts are highlighted with an orange background like this one.

A.3. Python Editor

After entering `EditPythonScript` one can see the editing environment (see Figure 1) which is split into several areas:

- The area on the left shows all available libraries (see Figure 1, orange area). It includes the `<python>` standard library, plus libraries called rhinoscriptsyntax, scriptcontext and Rhino. You’ll especially need rhinoscriptsyntax, which contains Rhino specific instructions.
- The area on the right shows the script code window in which new scripts can be written, displayed and edited (see Figure 1, green area). It has a syntax highlighting feature which displays programming language elements in color so as to make them easier to identify and check (e.g. the command “print” in the example below).
- The top toolbar contains a green “play button”. Once clicked it executes the current script, i.e. the code that was written in the script code tab.
- At the bottom you will see the output window in which status codes and error messages will be displayed once the program is running (see Figure 1, blue area).

Let us now enter some basic code in the script tab, without actually knowing what it does:

- Enter `EditPythonScript` in the command line of Rhino.
- In the script code window enter the following lines:

```python
1 # The next line will log Hello, Python on the console
2 print("Hello, Python!")
```

---

\(^3\) https://www.rhino3d.com/de/sales/europe/Austria/all/ (10.03.2018)

\(^4\) https://www.archlab.tuwien.ac.at/raum-pcl.html (12.03.2018)
• In order to execute the code, choose the “play button” (green arrow) that is available in the top tool bar.
• Examine the output window (blue area in Figure 1) which should display the message “Hello, Python!”.

The first program starts with a comment in line 1 (everything after # is ignored). It goes on to the print command in line 2, outputting the text “Hello, Python!”. We can also create our own commands (also see Second Act: The Play and its Script on page 21), however this has to be done in two steps: First we have to define what happens when that command is called, then we actually call it:

Program 1: Our first command

<table>
<thead>
<tr>
<th>Line</th>
<th>Code</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>import rhinoscriptsyntax</td>
</tr>
<tr>
<td>2</td>
<td>def start():</td>
</tr>
<tr>
<td>3</td>
<td>rhinoscriptsyntax.MessageBox(“Test”)</td>
</tr>
<tr>
<td>4</td>
<td>start()</td>
</tr>
</tbody>
</table>

In line 2, we define a command called start, which displays a message box (line 3) which you can quit by hitting OK. However, defining a command does not mean that it is executed. For that, we use start() in line 4.

![Program 1: Our first command](image)

Figure 1: Rhino Python Editor with its three areas: libraries (orange), script code window (green) and output window (blue).

A.4. Obtaining Help

An important topic for new programmers is the possibility to obtain documentation and help. For example, it is not clear from reading the example code in Program 1 what MessageBox(“Test”) means. In order to clarify, select the word “MessageBox” and hit F1. You may alternatively use the Help Menu and click ? Python Help. This brings up the help concerning MessageBox, which “displays a windows message box” (if not then type in MessageBox in the Index menu of Python Help).
Searching for help is the daily bread of a programmer. Neglecting to read the documentation is considered to be extremely impolite, and has since the 1970ies been punished by programmer's proverbs such as RTFM (“Read The Fucking Manual”), GIYF (“Google Is Your Friend”) and so on.

So let's have a closer look on the topic. If one faces a problem when programming or if one does not know what to do, there are several possibilities to get help:

1. Read the Fucking Manual (RTFM).
2. Search the Fucking Web (STFW); Google it up.
3. Not found any help? Go back to step 1.

Especially step 1 is important and should be devoted ample time. You can invoke Help via the menu Help or the F1 key (as is the case for all programs under Windows). Now you can identify three options:

- The **Content** tab includes information about the rhinoscript package, which gives an overview about Rhino specific functions. They are defined in different modules that can be called within the rhinoscript package. It also contains links to getting started tutorials and documentation on how to open sample scripts.
- The **Index** tab lists keywords in alphabetical order. This will typically be the first step to solve a particular problem (e.g. look up commands).
- While Index only searches headers, the **Search** tab includes the whole content. In most cases Search is used, if nothing can be found in Index.

Using help is not a luxury but rather the most basic technique which you will need. In addition, most programming environments come with a feature called IntelliSense or code completion which can help you look up commands: If you type “rhinoscriptsyntax.,” in the code window, a list of possible commands appears. The desired name can be selected using the arrow keys and inserted using the tab key.

### A.5. Debugging

In programming it is often required to run the programs line-by-line in order to check for correctness or simply for understanding what a piece of code does.

The term debugging originates from the times when computer consisted of vacuum tubes. Such an environment invited bugs to nest (since most of them like it warm), which caused disorders. Therefore, each time one had to check the hardware for bugs before starting a computational process.

In the 1940ies it was U.S. Navy Admiral Grace Hopper, who, for the first time, discovered that a moth was stuck in a relay of the rather largish Mark II computer, preventing it from properly operating. The moth (“bug”, see Figure 2) was removed and taped to a log book, which is now on display in the Smithsonian National Museum of American History in Washington D.C. Next to the attached moth she wrote:

> “… First actual case of bug being found.”
Today, the activity of debugging has shifted from hardware defects to the detection of logical errors in a program. In software debugging, the program is executed until an “important line” - e.g. an instruction which has failed in a previous execution. At this position the program is interrupted and the execution can now be inspected line-by-line. Debugging does not correct syntactical errors, which is already done by the compilation process before the program is executed. Debugging is rather semantic, i.e. one checks the result or the intermediate steps for “correctness”. Typical cases are:

- The program crashes, giving the line number of the instruction which caused the crash before it does (most common case). One will thus want to halt execution exactly at this line in order to see what went wrong.

- The program runs until the end, but does not provide the expected results. Most likely one will need to stop at the first line and inspect the whole program line-by-line, double-checking whether any calculations have gone wrong. It might help to have pen and paper nearby in order to first calculate the expected outcome of the program by hand, and then compare that to what the program actually produces.

- The program runs forever (it never comes to an end). This can be caused by several factors - the program may wait for a resource that is currently not available (e.g. a printer is assumed to be connected, which it is not) and keeps retrying; such an infinite repetition is the most common cause of this problem.

Figure 2: Grace Hopper finds the first bug in 1947.

In practical terms, the usual technique for starting debugging:

- Setting a line where the execution will stop (breakpoint): In our example of Program 1, try clicking left of line 3 (the line that reads rhinoscriptsyntax.MessageBox("Test")). A red dot similar to the one in Figure 3 should appear. If you cannot set set a breakpoint then probably the line on which you clicked is empty or contains no executable code (e.g. a line containing only a comment, as to be found in line1 of the example on page 12). However, it may also be that you did not click left beneath the line number (most common case).
In VBA you cannot set a breaking point on lines starting with Dim (see later on variable declarations).

- Stepping through the code line-by-line: start the program using the Play button (green arrow, see Figure 3) in the tool bar and observe how the program stops at the set breakpoint.
- After a breakpoint is reached you can continue by clicking the Play button again. In this case the program will resume until the next breakpoint or until the end of the program if no more breakpoints are set.
- Another option is to continue line by line. There are two options in that case, Step Over and Step Into (see Figure 3), which we will now examine in further detail:
  - Hitting Step Over tells the program to continue to the next line of code, if that exists.
  - Step Into tells the program to try jumping “into” the command found at the current line. In our case, this command is rhinoscriptsyntax.MessageBox which is defined in a separate file called ‘userinterface.py’ which comes with your Rhino program.
- Try pressing Step Into now: The program will open a file ‘userinterface.py’ and positions the cursor (indicated by a yellow arrow, see again Figure 3) on the first line within MessageBox command.
- There is also the possibility to jump back to after the calling line using Step Out (Figure 3).
- Further observations: The “variables” tab at the bottom shows all momentarily defined values. If you are still in the MessageBox(), you will see multiple entries listed there: Each has a name, a value and a type (int, string, None, etc.). Sometimes these entries also have a [+] sign which allows you to expand their contents - typically when dealing with lists and objects (presented later).
- Finally, you may also hit the Stop button (rightmost button in Figure 3) if you want to stop execution immediately, without running a program to its end.

Figure 3: Debugging in the Python Editor.
B. First Act: The Actors

[in which data types and variables appear on our mental stage]

ADDNUMBERS begins. After the curtain lifts, there are three actors on the stage: \( a \), \( b \) and \( result \). Taking a closer look at them, we realize that they are all holding a number in their hand (although we do not know exactly which number this is). \( a \) and \( b \) walk over to \( result \) and show it the numbers they are holding in their hands. \( result \) sums these up in its mind and changes the number he holds in its hand to the outcome. The curtain closes. The program ends.

This is a dramatized version of a program that simply adds two numbers. There are two things which must be distinguished in this context:

- The actors \( a \), \( b \) and \( result \) are called variables. Their primary role is to hold values, i.e. numbers, sequences of characters and so on.
- The script that acts on the variables is called the program flow. In our case, there was only one instruction present, which required \( result \) to sum up the values of \( a \) and \( b \).

B.1. Introducing Values, Data Types and Variables

A value is simply a piece of data - e.g. 12, “this is a test” or True. Values have an associated data type:

- Whole numbers (e.g. 12345) have the data type integer.
- Floating-point numbers (e.g. 12.345) are called float. Attention: although in German it is common to use a comma for the decimal mark (12,345), in programming you have to use a decimal point (12.345).
- Sequences of character (e.g. “Abracadabra”) are called string. The quotation marks at the begin and end are necessary. You may use single or double quotes (‘Abracadabra’ is valid as well), but not mixtures (“Abracadabra’ and ‘Abracadabra” are wrong).
- Logical values (True or False) are called booleans.

Variables are named containers for values. Instead of writing 12.345, you could introduce a variable called radius, set that to 12.345 and refer to that multiple times in your program:

Pseudo Code:
```
# create a variable called radius and fill it with 12.345
```

Python:
```
radius = 12.345
...
print(radius * radius + radius)
```

In python, declaring variables and filling them is done in one step. Other languages split that into

VBA:
```
Dim radius As Double
radius = 12.345
```
B.2. More on Variables

We already learned that variables hold values. Generally spoken they reserve memory locations in order to store these, requiring different size in memory according to their data type. Some programming languages thus require to specify a data type when declaring a variable (strictly-typed languages).

<table>
<thead>
<tr>
<th>VBA for AutoCAD: Declaration</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Description</strong></td>
</tr>
<tr>
<td>declare variable with the name “a” which holds a floating-point number</td>
</tr>
<tr>
<td>initialize the variable a to 1.5</td>
</tr>
</tbody>
</table>

*Table 1: VBA – Example for declaring and initializing*

After declaration, we might initialize a variable to hold a specific value. If the initialization is omitted, the programming language will assign a default value to the variable, depending on its data type.

If the protagonists of your program are numbers, you have two choices: **Integers** store whole numbers while **Doubles** store floating-point numbers. Table 2 lists the typical declaration of these two types:

<table>
<thead>
<tr>
<th>Characteristics</th>
<th>Declaration</th>
<th>Initialization</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>Integer</td>
<td>Dim i As Integer</td>
<td>i = 0</td>
<td>0</td>
</tr>
<tr>
<td>Double</td>
<td>Dim d As Double</td>
<td>d = 0.0</td>
<td>0.0</td>
</tr>
</tbody>
</table>

*Table 2: VBA – A few simple data types*

Trying to assign a value of another data type to such a variable will produce an error. Python, on the other hand, is an example of a dynamically-typed language - variables can contain values of any type:

<table>
<thead>
<tr>
<th>Declaration in Python</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Description</strong></td>
</tr>
<tr>
<td>declare variable “a” and fill it with 1.5 (which is a float value)</td>
</tr>
<tr>
<td>now fill the variable with a string</td>
</tr>
</tbody>
</table>

As shown in the example above, it is perfectly ok to assign values of different data type to the same variable (although we would generally advise against doing so because it is easy to introduce bugs in this way - e.g. by forgetting that a is a string and thus taking the square root of it later on).
To use a stored value, one simply gives the name of its variable:

```python
# display the content of a:
rhinoscriptsyntax.MessageBox(a)
```

A variable can take the value of another variable as well:

```python
a = 10
# assign the value of a to the variable b
b = a  # by the way, comments can be written after commands as well
```

### B.3. Working with Numbers

As mentioned, floating-point numbers are written using a decimal point (12.3), integers without (12).

**VBA for AutoCAD: Numbers**

If you assign an integer to a floating-point variable (of data type *Double*), the value will be implicitly converted (the value 0 becomes 0.0). Vice versa, floating-point values that are assigned to an *Integer* variable will be rounded to the nearest integer (0.6 becomes 1; 0.4 becomes 0) which is a common source of frustration for many beginning programmers.

Working with numbers is straightforward – you can use the standard operators +, -, / and * for performing simple calculations. *Program 2* demonstrates the concepts we have mentioned so far, plus some new ones, which will be elaborated after the code listing.

**Program 2:** Simple calculations using doubles and integers

<table>
<thead>
<tr>
<th>Line</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td><code>i = 10</code> create a new variable i and assign 10 (integer)</td>
</tr>
<tr>
<td>2</td>
<td><code>i = 1 + 4 * (2 / 10)</code> assign 1 + 4 * (2 / 10) to the variable i (floating number)</td>
</tr>
</tbody>
</table>

In line 1 the variable *i* is initialized with the value 10. Obviously, this is an *integer*. In the next line the variable is automatically changed to a *float*. This is called automatic type conversion and happens behind the scenes if python can figure out what to do.

### B.4. Manual Type Conversions

In seldom cases where python cannot do that automatically, you can convert types manually by calling `str()`, `float()` and `int()`.
The most common case where you will need type manual conversions is when you print something to the console. Printing generally takes the form

```
print(something [+ something...])
```

where something is a string and [... ] denotes an optional part where one or more strings are appended (“+”) to the first string. When used on strings, this works just as it should:

```
print("Hello" + " " + "World!")
```

However, when appending a non-string, Python throws an error:

```
print("PI is " + 3.14) # unsupported operand type(s) for +: ‘str’ and ‘float’
```

In these cases, one must manually convert the second part into a string using str(...):

```
print("PI is " + str(3.14)) # => "PI is 3.14"
```

Another case where an automatic type conversion fails is given in the following example, which queries the type of a variable using the function type():

**Program 3:** Data type in Python

<p>| | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>i = 10</td>
<td></td>
</tr>
<tr>
<td>2</td>
<td>print(&quot;type is: “ + str(type(i)))</td>
<td>prints “type is: int”</td>
</tr>
<tr>
<td>3</td>
<td>i = 1 + 4 * (2 / 10)</td>
<td></td>
</tr>
<tr>
<td>4</td>
<td>print(&quot;type is: “ + str(type(i)))</td>
<td>prints “type is: float”</td>
</tr>
</tbody>
</table>

**B.5. Intermediate Summary**

We have learned how to use variables. The following questions might help deepen your knowledge:

1. How do you declare a variable in Python and how in VBA? In which of the two must you declare the variable first and initialize it in a second step?
2. What is the data type of the value “blah”?
3. When do you need to convert values manually?
C. Second Act: The Play and its Script

[in which functions enter our mental stage]

“A boy wizard begins training and must battle for his life with the Dark Lord who murdered his parents.” (synopsis of J.K. Rowling’s “Harry Potter and the Sorcerer’s Stone” by Randy Ingermanson)

From the outside, a play is little more than a title and a short summary as exemplified above. The exact details stated in its script are usually of less concern for an audience, which considers it as a black box through which the main characters move during the course of a story. The actors and the director, on the other hand, need detailed instructions on how to perform their parts. This is stated in the script which - most of the time - the audience has not read (nor are they willing to do so - they are customers after all).

The same is true for programming: Most of the time you will be using others’ code without especially caring about how it works, as long as produces the results you are expecting it to (black-box thinking). The make that mode of thinking possible, programming languages package pieces of functionality into commands. If you supply these with the necessary inputs, these will produce outputs without requiring you to know exactly these get computed. The same happened also during you basic math education - did you know how the functions given in Figure 4 are actually computed?

\[
\begin{align*}
\sin(0) &= 0 \\
\cos(0) &= 1 \\
\sqrt{4} &= 2 \\
\sqrt{\cos(0)} &= 1 \\
\max(1, 2) &= 2
\end{align*}
\]

\[\text{Figure 4: Left: Mathematical calculations. Right: Seen as flow chart.}\]

In this course, we will be exploring both sides - use and definition of commands.

C.1. Python Functions

In Python, commands are called functions. We distinguish between their definition (i.e. the “script”) and its use:

- Defining a function means writing our code underneath a `def`, indented with either spaces or tabs:

```python
def name ( [input] ):
    ...code...
```
*name* defines how the function is called. It is followed by round brackets in which you optionally write inputs that the function needs (more on this later, at the moment one can simply leave that away):

```python
def name ():
   ...code...
```

After the round brackets follows a double point (:), then comes your code. A complete example would be:

```python
def MyFunction ():
    print("Hello World")
```

- If you want to run the function we just defined, you need issue a function call by writing the name of the function followed by round brackets, e.g.

```python
MyFunction()
```

This tells Python to (1.) look whether it can find a function definition for MyFunction and 2.) run all the commands contained therein. Because of point (1.), you will always need to define the function *before* calling it:

```python
def MyFunction ():
    print("Hello World")
MyFunction()
```

### C.2. Defining Functions, Passing Inputs, Receiving Outputs

The general form of a function definition in Python is:

```python
def name ( [input] ):
   ...code...
   [return output]
```

A function is a black box that processes any given input and may produce one value as output. For example, remember \( \sin(x) \) which processes the supplied number “\( x \)” and returns you the sinus of \( x \) as output. This output can then be saved to a variable or printed to the console:

```python
import math
a = math.sin(13)    # call function sin with 13 as input => outputs 0.22
```
Input and output are both optional (also refer to the example presented further below):

- You define inputs by writing one or more names (separated by commas) into the round brackets of a `def`. Through these names you can then access the passed values (e.g. `x` in the case of `sin()`).

- One output can be defined by using `return` followed by a value. Python will take this value and return it to the calling code, which can then save it e.g. into a variable:

```python
def math.sin(x):
    ...code to compute the sinus of x...
    return ...result of the calculation...
def replace(needle, haystack, replacement):
    ...code to replace string “needle” in “haystack” with “replacement”...
    return ...string with applied replacements...
```

In order to call a function which expects inputs, one needs to put values or variables (separated by commas) in the round brackets of a function call. The returned output can then be printed or saved to a variable:

```python
import math
print(math.sin(13))                    # input: 13
# output: 0.22 (printed to console)
a = replace(“bra”, “Abracadabra”, “X”) # inputs: “bra”, “Abracadabra” and “X”
# outputs: “AXcadaX” (saved to a)
```

There are two caveats in that context: Failing to give a function the inputs it needs will result in an error:

```python
import math
math.sin() # sin() takes exactly 1 argument (0 given)
```

One the other hand, assigning the output of a function that does not `return` any produces “None” (Python’s way of saying that the output is “nothing”):

```python
b = MyFunction() # MyFunction does not produce output, b therefore is “None”
```

Textual programming languages allow you to return exactly zero or one outputs - unlike in graphical languages (e.g. Grasshopper, Dynamo), which let you have any number of outputs. Python however has a syntax which allows you to return multiple values and assign them to variables in the following fashion:

```python
def MultipleOutputs:
    return (1, 2, 3)        # pack 1, 2, 3 into a tuple and return it
c,d,e = MultipleOutputs() # unpack the tuple into variables c, d and e
```
Technically, returning multiple values uses a trick: The output values 1, 2 and 3 are packed into a tuple which is returned and unpacked into three variables. More on tuples will be presented later.

---

**VBA for AutoCAD: Subs and Functions**

VBA distinguishes between functions that produce output ("Functions") and functions that do not ("Subs"): 

Definition of a Sub in VBA:

```vba
Sub name (input)
    ...code...
End Sub
```

Definition of a Function in VBA:

```vba
Function name (input) as data type of output
    ...code...
    name = some value
End Function
```

A *Function* is essentially defined the same way as a *Sub*, however there are two differences: First, the programmer must state the data type of the output (we know of *Double* or *Integer* at the moment). Second, the output has to be set to the result of the computation, which is written as `name = some value`. A more concrete example in VBA is given in the next section.

---

**VBA for AutoCAD: Defining Inputs**

In VBA the `Dim` statement is omitted for parameters (however `as` declaration is still needed):

```vba
1  Function Sum(a As Double, b As Double) As Double  Input two Doubles, outputs one Double
2   Sum = a + b  Set output directly to a + b
3  a = 1.5
```

---

**C.3. Intermediate Summary**

We have had a look at simple calculations from both the outside (*using functions*) and inside (*defining functions*). We have also looked into *Functions* with and without output. Here is a program which you can use to test and deepen your knowledge:

**Program 4:** What does this program do?

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>def Sum(a, b)</td>
</tr>
<tr>
<td>2</td>
<td>c = a + b</td>
</tr>
<tr>
<td>3</td>
<td>return c</td>
</tr>
</tbody>
</table>
C.4. Test Case: Writing a Function that “Rolls the Dice”

Until now, the presented functions were highly artificial given their scope and purpose. We now wish to come to a more practical application of the gained knowledge, in form of a function that can produce a number between 1 and 6:

Program 5:  

<table>
<thead>
<tr>
<th>Line</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td><code>import random</code></td>
</tr>
<tr>
<td>2</td>
<td><code>def RollTheDice():</code></td>
</tr>
<tr>
<td>3</td>
<td><code>a = random.random()</code></td>
</tr>
<tr>
<td>4</td>
<td><code>return a</code></td>
</tr>
<tr>
<td>5</td>
<td><code>RollTheDice()</code></td>
</tr>
</tbody>
</table>

In line 1, we load the random library which contains functions for working with random numbers. It contains the function random (written as `random.random()`) that returns a floating-point number between 0 (inclusive) and 1 (exclusive). This is impractical for a function called RollTheDice(), which rather should produce something in the range 1 to 6. Another point for due criticism is that the result of RollTheDice is never saved into a variable, which would actually make sense for subsequent calculations.

A second attempt. We will now be using another function called `random.randint()` which expects two inputs - a lower bound and an upper bound. The changed program will produce something in the needed range \[1..6\]. Furthermore, we will save the output of RollTheDice into a variable b which could be used later on in the program:

Program 6:  

<table>
<thead>
<tr>
<th>Line</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td><code>import random</code></td>
</tr>
<tr>
<td>2</td>
<td><code>def RollTheDice():</code></td>
</tr>
<tr>
<td>3</td>
<td><code>return random.randint(1, 6)</code></td>
</tr>
<tr>
<td>4</td>
<td><code>a = RollTheDice()</code></td>
</tr>
<tr>
<td>5</td>
<td><code>print(a)</code></td>
</tr>
</tbody>
</table>

A closer look at the program reveals that we have not used an intermediate variable inside RollTheDice; rather, we had that function return the result of random.randint immediately in line 3. In line 4, we have stored the output of RollTheDice in a variable a, which we used as input for print in line 5.

The library random contains many useful functions, e.g.
random.random() returns a random float $x$, $0.0 \leq x < 1.0$ (exclusive)
random.uniform(1, 6) returns a random float $x$, $1.0 \leq x < 6.0$ (exclusive)
random.randint(1, 6) returns an integer between 1 and 6 (start and end inclusive)
random.randrange(0, 7, 2) returns an integer as even number between 0 and 7

Instead of writing random.name of function all the time, one may also import the names all functions in that library (works also for other libraries):

```python
from random import *
a = randint(1, 6)
```

Another extension would be to pass in the number of sides of the dice as an input. Using that functionality, one can then simulate dice with any number of sides:

**Program 7:** Random values

```python
1 from random import *
2 def RollTheDice(sides):
3     return randint(1, sides)
4 print(RollTheDice(6))
```

**VBA for AutoCAD:** RollTheDice

```vba
1 Function RollTheDice(sides As Integer) As Integer
2    Randomize
3    Dim a As Integer
4    a=Int((sides-1+1)*Rnd+1)
5    RollTheDice = a
6 End Function
```

The first thing to notice is the declaration of the input “sides”, which is an Integer. The output is likewise an Integer, thus we write Function ... As Integer on line 1. Randomize (see line 2) reinitiates the random number generator, so that two runs of the program always end up producing different numbers. Rnd on line 4 then has the duty of returning a floating-point number between 0 (inclusive) and 1 (exclusive). Note that there are no inputs given to the function Rnd, therefore, the brackets must be omitted. In Line 5 the function is set to the result of the computation: RollTheDice = a.
VBA for AutoCAD: Random function

To achieve the same result as randint() in VBA we have to use a formula:

\[ \text{Int}((\text{Upper Bound}-\text{Lower Bound}+1) \times \text{Rnd}+\text{Lower Bound}) \]

The therein used \text{Int} function produces an integer out of a floating-point number by cutting off everything after the comma. The contrary of the Int function would be \text{Round}, which would round to the nearest integer. This time the result is a number between lower bound (inclusive) and upper bound (inclusive).

C.5. Intermediate Summary

We have had a look at a real program named RollTheDice which we used to compute a random number for a dice with a specified number of sides. Here are some points to deepen your knowledge:

1. Write the previously mentioned formula \( \text{Int}((\text{Upper Bound}-\text{Lower Bound}+1) \times \text{Rnd}+\text{Lower Bound}) \) as a function using random.random() in Python. The returned value should be between 1 (inclusive) and 6 (inclusive).

2. Is there a difference between defining an input for a function and introducing a variable in Python? Elaborate!

C.6. Advanced: Nested Function Calls

Until now we always used one function definition and one function call. However, you can (and often will) call a function from within another function you created:

```python
1  def RollTheDice(6):
2    ...as before...
3  def RollTheDiceTwice():
4    return (RollTheDice(6),RollTheDice(6))
5  first, second = RollTheDiceTwice()
```

Functions are a black box for functionality, as was said before. Often this functionality will be useful for many situations - and thus will be used multiple times throughout your code. This style of “write once, use multiple times”, is also good for fixing bugs - if there happens to be one in our function RollTheDice, then we need to only look into that function. If, on the contrary, we had duplicated the code of RollTheDice, then we would have to look through every one of its occurrences. Programmers thus come up with an important design principle that is called: “Don’t Repeat Yourself” (DRY) - if the same code appears multiple times in your source, make it into a function. More on design principles of good software are to be found in the excellent book “The Pragmatic Programmer. From Journeyman to Master” by Andrew Hunt, David Thomas and Ward Cunningham (1999).
D. Third Act: Alternative Plots

[in which logical values enter our mental stage]

Zeitgeist has produced theater plays in which the audience, rather than the director, controls the ongoing of events. At a certain point in the play, you might be asked: What should the actor do next, kiss the girl or tell her that he wants a divorce? “Divorce, Divorce”, I hear you scream, but wait: The important thing was that you had the option, right?

Options in computer terms always evaluate to True or False – which is called Boolean (or bool in Python). In Program 8 we show how to define new variable which is set to True (Python is case sensitive, therefore you really have to write True and not true) and then perform some basic evaluations using >, <, the logical and, logical or and the negation not:

Program 8: Working with Booleans

```python
1 def BooleanEvaluations():
2     b = True
3     b = 10 < 20
4     b = 10 > 20
5     b = 10 < 20 and 10 > 20
6     b = 10 < 20 or 10 > 20
7     b = not 10 < 20 or 10 > 20
8 BooleanEvaluations()
```

Among the comparisons that result in a bool are: “greater-than” >, “less-than” <, “greater-than or equal to” >=, “less-than or equal to” <=, “equality” ==, “inequality” != as well as the logical and, or and not, which require some more thought. And is True when both sides of the equations evaluate to True. Or is true if one of both sides is True. The negation not negates whatever comes after it, i.e. the expression not True would evaluate to False.

VBA for AutoCAD: Boolean

Note that variables of type Boolean have a default value of False if you do not specify otherwise.

Booleans are used for having conditions in the code, i.e. if some condition is True, perform a set of operations, else, perform another set. The general form for a condition is:

```python
if condition:
    block of code to execute if condition is True
else:
    block of code to execute if condition is False
```
The \texttt{else} part of the conditions can be left out if nothing is to be done else, giving you the stripped-down version of \texttt{if} ... \texttt{(Then}, indicated by “:” and indentation of the following line) ... \texttt{(End if}, indicated by unindentation of the following line).

\begin{center}
\textbf{VBA for AutoCAD: Condition}
\begin{verbatim}
If condition Then
    block of code to execute if condition is True
else
    block of code to execute if condition is False
End If
\end{verbatim}
\end{center}

A practical example using our previously-defined “\texttt{RollTheDice}” function shows that conditionals can be nested:

\begin{center}
\textbf{Program 9: Nested Conditionals}
\begin{verbatim}
def RollTheDice(sides):
    ... roll three-sided die, store result
result = RollTheDice(3)
if result == 1:
    print(“the die shows one”) # if result was 1, print “one”
else:
    if result == 2:
        print(“the die shows two”) # if result was 2, print “two”
    else:
        print(“the die shows three”) # print “three”

RollTheDice produces a number between 1 and \texttt{sides}
\end{verbatim}
\end{center}

Python’s required indentation makes sure that your code is easy to read even when nesting multiple \texttt{ifs} (or \texttt{whiles}, \texttt{fors} and so on - which will be presented later). A word of advice on using spaces or tabs in that context: Don’t mix both! Decide for one of either and then stick to that choice. Why? If you mix spaces and tabs and open your Python code in another code editor outside of Rhino, your statements will likely become mis-aligned:

\begin{verbatim}
if RollThe Dice(2) == 1:
    print “one” # this line was indented using two spaces
else:
    print “two” # this line was indented using a tab
\end{verbatim}

This is because editors convert tabs into a number of spaces internally, however the number of spaces they use differs. Had you written your code using either of both, then the lines would align perfectly.

A further note: The Rhino Python Editor automatically converts tabs to spaces per default (see setting \texttt{[x] Convert tabs to spaces under Tools > Options > Text Editor}), in order to prevent this error from happening.
D.1. Simpler Use of Booleans in Conditions

For this part, let us compare two code snippets which use a function that checks whether this computer is connected to the web (defined elsewhere) which returns a boolean:

```python
# snippet 1
haveNetwork = functionThatChecksWhetherThisComputerIsConnectedToTheWeb()
if haveNetwork == True:
    print “online”
else:
    print “offline”

# snippet 2
haveNetwork = functionThatChecksWhetherThisComputerIsConnectedToTheWeb()
if haveNetwork:
    print “online”
else:
    print “offline”
```

The only difference between the two snippets is the part “...if haveNetwork == True”. Technically this is nothing more than an equality comparison between `haveNetwork` and `True`.

- If `haveNetwork` is `True`, the result of this comparison is also `True`.
- If `haveNetwork` is `False`, the result is `False`.

“Hmmm”, I hear you say, “so basically this is the same as when you use only `haveNetwork`”. Exactly. This is why snippet 2 is written without “== True”.

D.2. Summing up this chapter

Booleans are used predominantly in if statements. An if checks if a supplied condition evaluates to True, then executes an enclosed block of code. Optionally, you might define a second block of code that is executed when the condition is False (else).

In the course of the chapter, we also mentioned that you should not mix spaces and tabs in indentation.

D.3. Questions

1. Compare a command with indentation to one without. Assume that there are three nested if-statements (i.e. an if in an if in an if) present, now speculate what would happen if you press the play button.
2. Initialize three variables w1, w2 and w3 with true. Then change w2 to the result of `(20 < (10 - 2))` and w3 by combining w1 and w2 by using the logical `and`.
3. Write the code for calling a message box and display w3 as message.
4. Write a function `max(a, b)` which returns `a` if `a > b`, and `b` in every other case.
E. Fourth Act: The Magic of Words

[in which strings enter our mental stage]

“Was it a car or a cat I saw” is a palindromic sentence which you can read from both sides and get the same result if you disregard punctuation: “was I tac a ro rac a t i saW”. Even though programmers are not generally known for playing with words, they do manipulate large amounts of text - think e.g. of Google search.

The data type for text is called **string**. Such values are given in between double or single quotes, i.e. “this is a string value” or “this is a string value”. A string offers several unique features which distinguish it from other data types:

- A string consists of a **sequence of characters**: The first character is character number 0, the second has the index 1 and so forth.
- The number of characters corresponds to the length of the string. The last character is thus always located at index (length - 1), because we start counting at 0.

The function `len(s)` calculates the length of a string, where `s` is a string whose length should be computed. The result of `len()` can be stored in a variable:

```
Program 10:  Length of a string

1  import rhinoscriptsyntax
2  def CalcLength():
3      s = “Abracadabra” initialize s with a string value
4      l = Len(s) calculate the length of s and give it back to a variable, called l
5      rhinoscriptsyntax.MessageBox(l) display result in a message box
6      CalcLength() run command CalcLength()
```

One can also access a specific character in a string using the notation `string[index]`. Since counting starts at zero, the 11 characters of the string “Abracadabra” would be accessible as follows:

```
Program 11:  Accessing characters of a string

1  s = “Abracadabra”
2  print(s[0]) “A”
3  print(s[1]) “b”
4  ... ...
5  print(s[10]) “a”
6  print(s[11]) index out of range: 11
```

We might also get a part of a string by using the notation `string[from:to]` where `from` is the starting index (inclusive) and `to` is the end index (exclusive) of the string to extract (this is called slicing):
Program 12: Substrings

1  s = "Abracadabra"
2  print(s[0:4])  "Abra"
3  print(s[1:11])  "bracadabr"

If to is greater than the length of the string or if it is omitted, the substring is extracted until the last character. If the from index is omitted, the substring is extracted from the first character on:

Program 13: Substrings again

1  s = "Abracadabra"
2  print(s[0:10000000000000000])  "Abracadabra"
3  print(s[7:])  "abra"
4  print(s[:4])  "Abra"

Beside extracting a single character or a substring one can also search for a specific string in another string. That is done with the command haystack.find(needle), where haystack is the string to search in and needle is the string to search for. Notice that you append find directly to a string you are searching in, e.g. “Abracadabra”.find("cad"). The function returns -1 if needle cannot be found in haystack, or the index at which the first character of needle is to be found in haystack:

Program 14: Find string in another string

1  import rhinoscriptsyntax
2  def FindStringInString():
3    s = "Abracadabra"  the string to be searched in
4    a = "cad"  the search term
5    b = s.find(a)
6    rhinoscriptsyntax.MessageBox(b)  the result is 4
7  FindStringInString()

As already mentioned when explaining manual type conversions, the "+" operator joins two or more strings together: "Rhino" + "Script" results in "RhinoScript". This can happen multiple times, i.e. "you " + "could " + "do " + "this " + "more " + "than " + "once."

Program 15: Join two strings together

1  def JoinStrings():
2    a = "Rhino"  first string
3    b = "Script"  second string
4    c = a + b  join together
5    print c
6  JoinStrings()
Manual conversions to string are necessary whenever a command expects a string but gets something different. One typical example is the `print()` function which was presented earlier:

```python
print("l: " + len("abc"))  # unsupported operand type(s) for +: 'str' and 'int'
print("l: " + str(len("abc")))  # l: 3
```

Two strings can be compared by the double equals sign "==". If both sides are equal the result is true, else it is false.

**Program 16**: Compare two strings

```python
1 import rhinoscriptsyntax as rs import library and give it a name
2 def CompareStrings():
3     rs.MessageBox("Rhino" == "Rhino") the result is true
4     rs.MessageBox("Rhino" == "Script") the result is false
5 CompareStrings()
```

In the above program, notice that we have renamed library `rhinoscriptsyntax` into `rs` during import (line 1). Subsequent calls can then use the much shorter form `rs.function` instead of `rhinoscriptsyntax.function`. Another option for shortening our code (which we have already encountered previously) would be to use `from rhinoscriptsyntax import *`, which makes all functions in `rhinoscriptsyntax` available without having to prepend the library name. In case you use multiple libraries, the latter approach is discouraged, as you might import from two libraries which have the same name for a function.

### E.1. Advanced Character Extraction and Slicing

We have so far gotten to know `string[index]` for extracting a character and `string[from:to]` for getting a substring (slice) of a string. You may also specify negative values for index `from` and `to`, as shown in the following example:

**Program 17**: Character extraction and slicing using negative indices

```python
1 s = "Abracadabra"
2 print(s[-1])  # get the last character -> "a"
3 print(s[-2:])  # get last 2 characters -> "ra"
4 print(s[:-2])  # get everything but the last # 2 characters -> "Abracadab"
```

In fact, the slicing operator can also take a third part called `step`, which lets you extract every “n-th” character from a string. If this `step` parameter is negative, then Python will walk through the string
from the right to the left in steps of step characters at a time. The following example clarifies these advanced uses once more and is used to reverse the string mentioned in the beginning of this part:

Program 18: Slicing using a specified step size

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>s = “Was it a car or a cat I saw”</td>
</tr>
<tr>
<td>2</td>
<td>print(s[::2]) # extract every 2nd character</td>
</tr>
<tr>
<td>3</td>
<td>print(s[::-1]) # get every first character from right to left</td>
</tr>
</tbody>
</table>

If you have not remembered every command that was presented herein, do not despair. A cheat sheet is given in the Appendix, showing what you can do with every type (see page 82). You can also use the help menu to find more commands on strings.

E.2. Summing up this chapter

We have encountered the String type. There is a variety of functions to be performed with strings, some of which are given in the appendix. Most of the time, though, you will want to concatenate strings using the + operator. Sometimes you will need to do a manual type conversion using str().

E.3. Questions

1. Find the position of the colon in the string s = “Mein Name ist: Killroy” and save it as a variable called indexOfDoublePoint. Use the position of the colon to extract the name and store it in a variable theNameIs. Join the string “Your name is: “ with the NameIs and display the result is a message box.
F. Intermediate Stage

[or two sides of the same coin]

F.1. Algorithmic Thinking

To think algorithmically means describing a process. This does not necessarily have to do with computers but can also relate to the real world:

Making a toasted cheese. ... a cheese toast is a simple slice of bread topped with melted cheese. To make it, the oven is your best bet. ...

... Toast the bread on one side and remove from the oven. Top the untested side with slices of your favorite kind of cheese, or a shredded variety. Return the bread to the oven so the bread continues toasting on the top side, melting the cheese at the same time. Remove from the oven when the cheese is bubbly and the toast is brown.¹

These instructions address a real person. When programming you will address a computer instead. The term algorithm comes from mathematics. It was coined by Muḥammad ibn Mūsā al-Khwārizmī, who, around 820, wrote the Arabic treatise on mathematics “Al-kitāb al-mukhtaṣar fī ḥisāb al-ğabr wa’l-muqābala” (“The Compendious Book on Calculation by Completion and Balancing”) . It contains calculation rules and – which is of much importance for us – the description of the number 0.²

F.2. Problem-centered strategy

Algorithmic thinking requires one to think of the problem first (problem-centered strategy):

• A large problem is split into several smaller parts that are independently solvable³.

• The act of finding a solution is decomposed into a step-by-step process.

Another difference between finding a solution in classical and computational design is that the latter tries to find one (best) solution for a specific (well-defined) problem rather than a huge set of possible variations for an (often elusive) problem domain.

Lawson states in his book “How Designers Think” (2006) that architects are rather solution-focused. In an experiment under “laboratory conditions” two different groups had to solve a given problem. One group comprised postgraduate science students and the other final year students of architecture. They had to arrange certain wooden blocks on a ground plan (similar to Tetris). However, they did not know which combination is right or wrong. The only way to find out, whether the arrangement

¹ https://www.wikihow.com/Make-Toast (13.03.2018)
² The word zero derives from the Arabic sifr “cipher”; the translation of Sanskrit sunya-m means “empty place, desert, naught”
³ A subsequent merge of each individual solution into an overall solution generally requires an own synthesis step, see Christopher Alexander’s “Note on the Synthesis of Form” (1964)
was a valid solution or not, was to enter it in a computer. The feedback was then either yes or no, depending on the saved rules. Lawson writes about the students:

\[\text{... The two groups showed quite consistent and quite strikingly different strategies. Although this problem is simple compared with most real design problems there are still over 6000 possible answers. Clearly the immediate task facing the subjects was how to narrow this number down and search for a good solution. The scientists adopted a technique of trying out a series of designs which used as many different blocks and combinations of blocks as possible as quickly as possible. Thus they tried to maximise the information available to them about the allowed combinations. If they could discover the rule governing which combination of blocks were allowed then they could search for an arrangement which could optimize the required colour around the design. By contrast, the architects selected their blocks to achieve the appropriate coloured perimeter. If this proved to be an acceptable combination, then the next most favourable coloured block combination would be substituted and so on until an acceptable solution was discovered. The essential difference between the two strategies is that while the scientists focused their attention on understanding the underlying rules, the architects were obsessed with achieving the desired result. Thus, we might describe the scientist as having a problem-focused strategy, and the architect as having a solution-focused strategy.}\]

This difference is exactly what complicates communication between architects and computer scientists. On the one side, the architect expresses his/her wishes with the words “it would be great if we could do it so and so, then we could also, ...”. On the other side, the computer scientist thinks about how to realize all wishes, which may already cause depressions. It is not possible to work together without understanding how the other side is thinking. On the one extreme there is an introvert programmer (nerd) and on the other an aloof architect (diva). Therefore, throughout the lecture we think problem-oriented and break down the whole problem into smaller parts before working on a solution. This will, for sure, also help in daily life.

G.  Fifth Act: We want to draw

[in which lists enter our mental stage]

When using drawing functions, Rhino expects the user to supply three-dimensional coordinates. So far, we know integers and floats each having one value; so how can one specify a variable that has three entries – e.g. (1.6, 2.5, 3.8)?

G.1.  We Need a List (an Array)

This is the point where lists/arrays enter the stage. An array is an ordered list of values of the same type, e.g. three booleans, four integers and so on, while a list is an ordered list of items which can be of any type. Python only knows lists (which is more flexibly than arrays). Program 19 gives a listing on how to define a list in Python:

<table>
<thead>
<tr>
<th>Program 19: Defining Coordinates as a List</th>
</tr>
</thead>
<tbody>
<tr>
<td>1  def definingACoordinate():</td>
</tr>
<tr>
<td>2    pos = []</td>
</tr>
<tr>
<td>3    pos.append(1.6)</td>
</tr>
<tr>
<td>4    pos.append(2.5)</td>
</tr>
<tr>
<td>5    pos.append(3.8)</td>
</tr>
<tr>
<td>6    definingACoordinate()</td>
</tr>
</tbody>
</table>

When a list enters the stage (see line 2 in Program 19) it contains nothing; no item, no value. In order to add an item, one has to use the function `append()`. This function does exactly what it says: it appends (add) an item with a value to the end of the array. The result is a list of certain items (in our case 3, see Program 19). An alternative way is to specify a list giving some initial values separated by colons:

| 1  def definingACoordinate():        |
| 2    pos = [1.6,2.5,3.8]             |

VBA for AutoCAD:  Defining Coordinates as an Array

<table>
<thead>
<tr>
<th>VBA for AutoCAD: Defining Coordinates as an Array</th>
</tr>
</thead>
<tbody>
<tr>
<td>1  Sub DefiningACoordinate()</td>
</tr>
<tr>
<td>2      Dim pos(0 To 2) As Double</td>
</tr>
<tr>
<td>3      pos(0) = 1.6</td>
</tr>
<tr>
<td>4      pos(1) = 2.5</td>
</tr>
<tr>
<td>5      pos(2) = 3.8</td>
</tr>
<tr>
<td>6      End Sub</td>
</tr>
</tbody>
</table>

initialize the 1st entry with 1.6,
the second with 2.5,
the third with 3.8
Defining Coordinates as an Array

Just as with regular variables, arrays are declared using the `Dim` statement. The size declaration (0 To 2) after the variable's name implicitly gives the number of entries, which is necessary with VBA. In our case the number of entries is three (0, 1 and 2). However, the size declaration could also run like `pos(1 To 3)`, which leads to three entries as well (1, 2 and 3). That means, the position of the entries starts with the first number in the declaration (usually and therefore in our case this is 0). After declaring the array, we initialize each of its elements using `pos(index) = value`. When you specify an index that is not in the defined range, VBA will raise an error. In the same manner as initializing an element, we can access a certain entry of the array by giving the variable's name and the position in brackets – `pos(0)` for the first value, `pos(1)` for the second value and so on.

If you have troubles in comprehending the concept of lists, the following analogy will help: As soon as a play has ended, the curtain drops. When the applause has reached an adequate volume, the curtain lifts again and you see all actors assembled in a line. “Look”, you might say, “the third one from the left, I found that she played really well”. Picking out the third actor (item) from the left was what we would do programmatically by using `actors[2]`.

**Hint!** In Python, the first index of an array is always zero-based (starting with the index 0).

But how about picking the third actor from the right? First we have to find the length of the list, that means the total number of items. This is achieved by the `len()` function, which we already know from strings:

```python
1 def findLenOfArray():
2    pos = [1.6, 2.5, 3.8]
3    numEntries = len(pos)  # get number of entries of the list
4    print(numEntries)     # result will be 3
5 findLenOfArray()
```

An array has a length (number of entries). The number of entries can be calculated in VBA by the `UBound()` function, which gives you the last index in the array, and the `LBound()`, which gives the first index:

```vba
1 Sub ArrayBounds()
2    Dim actors(...) As Double
3    Dim firstIndex As Integer
4    Dim lastIndex As Integer
5    firstIndex = LBound(actors)
6    lastIndex = UBound(actors)
7    sizeArray = lastIndex - firstIndex + 1  # calculate the length of the array; don’t forget to add 1!
8 End Sub
```

A list can store any data type. Lists can even contain other lists, e.g. `[[1,2],[3,4]]`. 
G.2. The Case of the Stairs

As a first full-fledged program, we want to develop a stair algorithm that produces a staircase in 2D, given the following parameters:

- StartingPoint – the starting point of the polyline should be located at (0,0,0);
- StepHeight – the height of a single step should be 18cm;
- StepDepth – the depth of a single step should be 32cm;
- NumberOfSteps – the number of single steps should be 2 for now.

Now comes the analysis phase. A step starts at a certain position in 3D space, initially this would be StartingPoint (point0 in Figure 5). From this position, we draw a line of length StepHeight (h) vertically upwards. This defines the second point of the staircase (point1). Then we draw a horizontal line of length StepDepth (d) to complete the first step. We already reached the third point (point2). The whole process is repeated from the current position to get the second step (fourth and fifth point; see Figure 5).

![Figure 5: Output of Program 22.](image)

The Pseudo Code (a description of the operating principles of an algorithm) runs like this:

```
Program 20: Pseudo Code of the program staircase

#define x, y and z as coordinates of a (changing) point and initialize x, y and z as starting point (0,0,0);
#define a list “point” with x, y and z of the starting point

#define a list “points” that saves all points sequentially
#add the first point of the staircase to the array “points”

#change y-coordinate for 1st point of first step and add point to points
#change x-coordinate for 2nd point of first step and add point to points

#draw polyline
```
G.3. Intermediate Stage: Rhinoscriptsyntax

Since you want to draw in Rhino, you will need the RhinoScriptSyntax methods library. This allows
the user to access Rhino’s geometries and commands. You’ll find the RhinoScriptSyntax in the left
window of the Python Editor (see Figure 6, left). If you choose a function, additional information will
appear in the bottom gray area (the output window, see Figure 6, right).

![Figure 6: Left: Contents of RhinoScriptSyntax. Right: Additional information about the command AddCircle().](image)

Throughout this course, we are going to use RhinoScriptSyntax, one example of which is given in
Program 21:

<table>
<thead>
<tr>
<th>Program 21: Drawing a circle</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 import rhinoscriptsyntax as rs</td>
</tr>
<tr>
<td>2 def DrawInRhino():</td>
</tr>
<tr>
<td>3 pos = [1.6,2.5,3.8]</td>
</tr>
<tr>
<td>4 rs.AddCircle(pos, 10)</td>
</tr>
<tr>
<td>5 DrawInRhino()</td>
</tr>
</tbody>
</table>

The AddCircle Function takes two parameters, a list of numbers (float or integer) defining the center
of the circle and a number giving its radius. For further information press F1 and search for “AddCircle”.
This brings up the help file on “AddCircle” with more elaborate description. As a shortcut, we have
also compiled a list of popular drawing commands as appendix (see page 82).

G.4. Continuing with the Case of the Stairs

We are now going to use the AddPolyline() function to draw a polyline. AddPolyline takes a list of
3D points as input (or more precisely a list of lists representing coordinates of the points). Note that
there must be at least two points in the array; if the list contains less than four points, then the first point and last point must be different.¹

Referring to the finished program (Program 22, also see Figure 5), there are several oddities which require attention:

¹ Compare help menu of Python
• The starting position is fixed to (0,0,0). The StepHeight and StepDepth are also fixed. Clearly, one should be able to pass these values into the command rather than defining it in the code (like StepByStep(StepHeight, StepDepth)).

• We notice that the code for the 1st step is the same as for the 2nd step.

You might have guessed it – these points smell like a proper cause to introduce something new that will fix all these problems.

**VBA for AutoCAD: Step program in VBA**

In VBA, the command `AddLightWeightPolyline()` takes an array of numbers representing coordinates of 2D points. That means we have to append the x- and the y-coordinate of every point. We start with \(x_0\) and \(y_0\) of point at (0,0). Every next step consists of two more points. We get the first point by adding the height to the y-coordinate of the previous point (0,0) and the second by additionally adding the depth to the x-coordinate. If all coordinates are saved in the array, it can be passed to the command `AddLightWeightPolyline()` which adds a 2D polyline:

```vba
1 Sub StepByStep()
2    Dim x As Integer declare current x-coordinate
3    Dim y As Integer declare current y-coordinate
4    x = 0 initialize with x-coordinate of starting point
5    y = 0 initialize with y-coordinate of starting point
6    Dim points(0 To 9) As Double declare array that will hold 10 coordinates of 5 points
7    points(0) = x add x-coordinate of starting point
8    points(1) = y add y-coordinate of starting point
9    'step 1
10   y = y + 18 add height for 1st step
11   points(2) = x add x-coor of 1st point of 1st step
12   points(3) = y add y-coor of 1st point of 1st step
13   x = x + 32 add depth for 1st step
14   points(4) = x add x-coor of 2nd point of 1st step
15   points(5) = y add y-coor of 2nd point of 1st step
16   'step 2
17   y = y + 18 add height for 2nd step
18   points(6) = x add x-coor of 1st point of 2nd step
19   points(7) = y add y-coor of 1st point of 2nd step
20   x = x + 32 horizontal point of 2nd step
21   points(8) = x
22   points(9) = y
23   ThisDrawing.ModelSpace. AddLightWeightPolyline(points) draw staircase: array is passed to AddLightWeightPolyline()
24   MsgBox(“Polyline drawn”)  
25 End Sub
```
In VBA there are some additional oddities which require attention:

- The algorithm seems to know that there are only two steps. Else, the sizing of the array "points" could not have happened in advance. Because the number of steps is fixed to 2, NumberOfSteps was never defined as variable.
- The algorithm uses integers. While this might be OK for now, we have to think about changing this is subsequent versions of the program, to also allow for stair depths and widths of non-integer type.

G.5. A Separate Command for a Single Step

Programmers hate code duplication, therefore coining the **DRY Principle** ("Don't Repeat Yourself"). **Code repetition** is error-prone and tedious to work through when changing software, the key to proper coding lies in trying to avoid it at all costs. A mechanism for coping with such repetitions was already given, namely the use of functions. If we could write a function that draws a single step and use that multiple times, we could eliminate a lot of code (see **Program 23**):

**Program 23: Second version of the step program**

```python
import rhinoscriptsyntax as rs

def SingleStep(x, y, z, StepDepth, StepHeight, points):
    y = y + StepHeight
    point = [x, y, z]
    points.append(point)
    x = x + StepDepth
    point = [x, y, z]
    points.append(point)
    return (x, y, z, points)

def StepByStep():
    StepDepth = 32
    StepHeight = 18
    x = 0
    y = 0
    z = 0
    point = [x, y, z]
    points = []
    points.append(point)

    #step 1
    x, y, z, points = SingleStep(x, y, z, StepDepth, StepHeight, points)

    #step 2
```

new command for a single step
add StepHeight to y-coordinate
1st point of nth step
append 1st point to list “points”
add StepDepth to x-coordinate
2nd point of nth step
append 2nd point to list “points”
return tuple of 4 elements: x,y,z,steps
set start position (x-coordinate)
set start position (y-coordinate)
set start position (z-coordinate)
write start position to a list with 3 positions (x-coor, y-coor, z-coor) representing a single point list for all points
1st step
get back new values of x,y,z,steps
We start off by giving our new function three coordinates \((x, y, \text{ and } z)\) that denote the current position in space. Adding \(\text{StepHeight}\) to \(y\) gives a next point, which we add to a list of generated points (see lines 3-5 in Program 23). Then, we add \(\text{StepDepth}\) to “\(x\)”, giving a further point, which we add to the points list (see lines 6-8). We return the current position \(x, y\) and \(z\) as well as the points list. Calling this function multiple times fills the points list (see lines 20-22). Note that the very first point must be manually appended to the points list before using our new function (see line 18).

G.6. Dynamic Arrays (only necessary in VBA)

VBA for AutoCAD: Challenges with the step program

In VBA, there is another point that really troubles the programmer’s mind. Have a look at line 6 of Step program in VBA, in which the size of the array is pre-calculated. Of course, this can be done in advance and is no error per se. However, from a programmer’s standpoint, it might be more convenient to extend the points array whenever new coordinates are to be stored.

Extension of an array at run-time can be done using dynamic arrays, i.e. arrays that can change size:

- A dynamic array is declared without size, i.e. \(\text{Dim points}\) \(\text{As Double}\)
- Before storing a new point into the array, the points array is resized to “one value more”. Resizing an array happens with the \(\text{ReDim Preserve}\) statement, i.e.:

\[
\begin{align*}
\text{Dim points() As Double} \\
\text{ReDim Preserve points(0 To 9) As Double}
\end{align*}
\]

\[
\ldots
\]

We see that instead of writing \(\text{Dim points}(0 \text{ To } 9) \text{ As Double}\) we use \(\text{ReDim Preserve points}(0 \text{ To } 9) \text{ As Double}\), thereby extending the previously empty array to 10 cells. Preserve means that VBA will preserve the contents of the Array when resizing, which of course only applies if we are extending an array that was previously non-empty.

There is an important point in extending an array by one cell. Remembering the previously presented \(\text{UBound}\) function, you could set the new size to \(\text{UBound(points)} + 1\), i.e.:

\[
\begin{align*}
\text{Dim points() As Double} \\
\text{ReDim Preserve points(0 To UBound(points) + 1) As Double}
\end{align*}
\]

\[
\ldots
\]
However, **UBound** does not like arrays that are empty – it simply crashes when trying to execute that code. It has no problems with filled arrays, though. Of course this smells like an **If** condition:

```vbnet
... 
Dim points() As Double
If you find out that points is empty Then 
    ReDim Preserve points(0 To 0) As Double 'make it one cell big
Else
    ReDim Preserve points(0 To UBound(points) + 1) As Double
End If
... 
```

We have come far, but we have to go even further. Why does this extension of the array and subsequent putting a value into it take place just inside my code? There should be a **Sub** for doing exactly this, since this could be used over and over for many different programs.

```vbnet
1 Sub appendTo(a() As Double, value As Double)
2  If (Not a) = -1 Then extend the array by one
3   ReDim Preserve a(0 To 0) As Double
4  Else
5   ReDim Preserve a(0 To UBound(a)+1) As Double
6  End If
7  a(UBound(a)) = value set last cell to passed-in value
8 End Sub
```

This program is what we would have in mind (and which is similar to the `append` function in Python). From the outside, you pass over an array of doubles (i.e. `a()` **As Double**) and a value to store. The **Sub** appends the value to the array, and that’s it. If you have no clue concerning line 1 “If (Not a) = -1 Then” – don’t worry, as we don’t understand that specific snippet of code, too. This is a workaround taken from the Internet which tests whether an array is empty. In the words of the Author of the hack: “[the code is] a slightly obscure but quite neat hack to check if a dynamic array has been initialized”. So be it.

Apart from the check for the empty array, however, everything should be clear. The array is extended with `ReDim Preserve`, then we set the last cell of the array to the passed-in value. Changes that are made to the array stay even after the **Sub** has finished. This is true per default for every parameter you pass into a **Sub** or **Function** – **if you change it, the changes are kept**.

In Python it is not necessary to write a program like “appendTo”, since this is already included in the function “.append()”.

### G.7. Summing up this chapter

We have seen that there are variables that can take sequences of values, i.e. **lists** (Python) and **arrays** (VBA). While an array is an ordered list of values of the same data type, a list is an ordered list of items which can be of any data type. Each value (i.e. each item or entry) can be accessed and changed individually. Lists and arrays are needed to store coordinates, a circumstance we often encounter when working with drawing functions.
VBA for AutoCAD: Summary on arrays

In the course of programming, we have seen that it is possible to pre-allocate arrays and fill them programmatically in the course of the program. However, defining such static arrays might not always be easy – therefore, we have introduced dynamic arrays, which can store an amount of values that is not known in advance. We have implemented a utility program that can append a value to an array, and have thereby seen that it is possible to change values passed as parameters.

G.8. Questions

1. What is an array?
2. Using whatever help you get, figure out
   a) what a multi-dimensional array is
   b) how you can define a three-dimensional array with 3x3x3 entries.
3. Define an array with three entries: “Rhino”, “Python” and “rules”. Save the third character of the second entry in a new variable.
### H. Sixth Act: We Want to Avoid Writing Unnecessary Code

[in which loops enter the stage]

Coming back to the criticism over the repeated step code in our staircase program (see Program 22), we need something new that can repeat code (i.e. the same lines are executed multiple times).

In the previous chapter we described a command that draws a staircase by repeating the part of a single step. In our particular case we called the command `SingleStep(x, y, z, StepDepth, StepHeight, points)` twice. But how about 1,000 stairs, I ask? This would again produce repetition in the form of all these calls to `SingleStep(...)`. No, there has to be some other construct that can really solve this problem. This construct is called a **Loop**. A simple loop is to count up:

**Program 24:** Pseudo Code of a loop

```plaintext
#define variable x and initialize it with 1
#repeat unless a termination condition is met
  #increase the value of x by 1
#end of loop
```

In programming we have different forms of loops. They differ in the position of the condition. With some types of loops the condition is asked at the very beginning. Only if it is true the block inside is entered. In all other cases the program continues after the end of the loop. We call loops with termination condition at the very beginning **pre-test loop**. The loop checks the condition before the block is executed. Loops that check the condition after the block are called **post-test loop**. In this case the block is passed through at least once.

#### H.1. While Loop (Pre-Test Loop)

The part “unless a termination condition is met” from the Pseudo Code example equals a logical expression (true or false). This looks quite similar to an **If**, you might say. This is completely right – a **While** is like an if-condition, only that the if-condition executes the enclosed block of code one time if the condition is true. On the contrary, the while-loop executes the block over and over again, as long as the condition is true. “x > value” would be a common condition (in our example below `x > 10`). That means, the loop will be repeated until `x = value + 1` (in our example `x=11`). I.e. the block inside the while loop is repeated as long as the condition is fulfilled, i.e. true.

**Program 25:** While loop – count-up example

```python
def loop():
    x = 1
    while x < 10:
        x = x + 1  # increase x by 1
```
**Hint!** The loop continues as long as the condition remains true. That means: as long as \( x \) is smaller than 10, the counter (\( x \)) has to be increased by 1. All commands of the while block are executed until the condition is not met any more. So, if you forget to increase the counter (\( x \)) the loop will continue infinite number of times. This is called endless loop (pitfall!). Without counting up, the condition is always true since the variable (\( x \)) always equals 1 and fulfills the condition \( x < 10 \).

The general form of a while loop runs:

```
While condition:
    block of code to execute if condition is True
```

**VBA for AutoCAD: While loop (general form)**

1. `While` condition
2. `block of code to execute if condition is True`
3. `Wend` indicates the end of the while loop

With this knowledge in mind, the reimplementation of our staircase program can be conducted (see Program 22). The new version will be cleaner, shorter and easier to read.

First, we have to think about, which parts can/should be repeated. From Program 23 we already know which parts belong to a single step:

**Program 26: Single step of staircase program**

1. \( y = y + 18 \) add StepHeight to y-coordinate
2. point = \([x,y,z]\) 1st point of nth step
3. points.append(point) append 1st point to list “points”
4. \( x = x + 32 \) add StepDepth to x-coordinate
5. point = \([x,y,z]\) 2nd point of nth step
6. points.append(point) append 2nd point to list “points”

**VBA for AutoCAD: Single step of staircase program**

1. \( y = y + 18 \) height of step
2. `ReDim Preserve points(0 To ...) As Double`
3. `points(...)` = `x` depth of step
4. `points(...)` = `y`
5. \( x = x + 32 \)
6. `ReDim Preserve points(0 To ...) As Double`
7. `points(...)` = `x`
8. `points(...)` = `y`
For more flexibility we have to rewrite the code:

**Program 27: Pseudo code of loop**

```
#initialize a variable “step” with the value 0

while step < NumberOfSteps:
    #add a single step (its points) while increasing height and depth of coordinates

#draw polyline
```

The final version of the program uses the while-loop, repeating the step drawing process for as many times the user wishes. Loops and commands (functions) can help in keeping code free of repetitive parts (this was referred to as the DRY principle).

**Program 28: Third version of the step program**

```
1 import rhinoscriptsyntax as rs
2 def GenNStairs(NumberOfSteps):
3     x = 0
4     y = 0
5     z = 0
6     point = [x,y,z]
7     points = [
8         points.append(point)
9     step = 0
10    while step < NumberOfSteps:
11        #add a single step (its points) while increasing h & depth of coors
12        y = y + 18
13        point = [x,y,z]
14        points.append(point)
15        x = x + 32
16        point = [x,y,z]
17        points.append(point)
18        step = step + 1
19    rs.AddPolyline(points)
20 GenNStairs(10)
```
VBA for AutoCAD: Second version of the step program

1 Sub GenNSteps(NumberOfSteps As Integer, startx As Double, starty As Double)
2   Dim points() As Double
3   Dim x As Integer
4   Dim y As Integer
5   x = startx
6   y = starty
7   appendTo points, x
8   appendTo points, y
9   Dim counter As Integer
10  counter = 0
11  While counter < NumberOfSteps
12    y = y + 18
13    appendTo points, x
14    appendTo points, y
15    x = x + 32
16    appendTo points, x
17    appendTo points, y
18    counter = counter + 1
19  Wend
20  ThisDrawing.ModelSpace.AddLightWeightPolyline(points)
21 End Sub

H.2. For-Loop (Pre-Test Loop)

Another kind of pre-test loop is the so called For-loop. In contrast to the While-loop, counting-up is done automatically (see line 2):

1  def ForLoop():
2    for i in range(1, 9):
3      print i
4    ForLoop()

The term “in range(1,9)” means that the counter (i) starts with the number 1, increases its value by 1 and repeats the loop until i = 9. The condition returns false as soon as 9 is reached. Inside the for-block the value of the counter (i) is printed in the output window. When you run the command, you’ll recognize that i = 8 is the last printed value for (i). This is because as soon as i = 9 the condition is no more valid and the loop stops (the program switches to the first line after the end of the loop).
**VBA for AutoCAD: For-loop**

1. Sub main()
2. Dim i As Integer
3. For i = 1 To 9
4. ‘here are commands
5. Next i
6. End Sub

In this case, the previous declared variable (i) starts with 1. All commands inside the loop are executed line by line. In “next i” the value of (i) is increased by 1. This is repeated until the value 9 (inclusive) is reached.

**H.3. Do-Loop (Pre-Test or Post-Test Loop) or While True**

In some program languages there is a do-while loop. Python has no such construct, therefore let’s first look at a do-while loop in VBA and then switch to a workaround in Python to achieve the same.

**VBA for AutoCAD: Do-while**

The do-loop can be used as pre-test or post-test loop. That means the condition can either be written at the beginning or at the end. We will have a closer look only on the post-test loop version (since we are already aware of two pre-test loops):

1. Sub main()
2. Dim x As Integer
3. x = 0
4. Do
5.   x = x + 1
6. Loop While x < 10
7. End Sub

In contrast to a pre-test loop, a post-test loop is executed at least once. Only at the very end of the loop the condition is tested. Even if the condition is not met from the very beginning, the block inside the loop is nevertheless executed. This is the big difference between a pre-test and post-test loop. At the end the condition is checked. If it holds true, the loop runs another time.

In practice post-test loops are seldom used. An example of their usage is the repetition of instructions in case of an error: first, some commands are executed; then one or more retries are started, to see if the error was only temporary. If the error still occurs after n-retries (defined as termination condition), the loop is finally terminated.

There is no do-while loop in Python. However, there is a similar construct that does the same with a while loop:
Program 29: Do-while in Python

1    def Condition():
2       i = 0
3       while True:
4          i = i + 1
5          print i
6          if i < 2:
7              break
8          print “finished”
9       Condition()

At the beginning of the while-loop the condition is in any case true. Therefore the following block of commands are executed at least once. Only in line 6 the actual condition is tested (as an if-condition). If the condition is not met, the loop finishes (using the command break in line 7) and the command continues at line 8.

H.4. Intermission: Nice Coding

At this point we want to repeat our advice about the correct indentation, which is essential for being able to write Python code. Other programming languages are not that strict, however, correct indentation makes reading the code much easier. This especially holds true if one revisits code after a longer period of time, or has to read code produced by someone else. Rules for nice coding:

- Insert an empty line before and after every function.
- Indent after a block starts. A block includes functions, conditions and loops. It is best to use a tab stop. Always use the same indentation (2 spaces or tab stop or ...).
- Comments can be helpful. Insert them before coding.
- Names of variables and commands should speak for themselves. This saves time for documentation.
- Split long calculations into shorter ones. No one will understand a*a+b*29+calculate(a,b,c).

Most of these rules are just recommendations and should make the code easier to read.

H.5. Summing up this chapter

The urge to produce a full-blown program has led us to the production of the code for GenNSTairs (see Program 28).
1. Write a program with a while loop. The variable \( x \) should be an empty string at the beginning. In the while block add continually the string “a” to the variable \( x \). Print the resulting string in the output window.

2. We learned about three different loops (while, for-next and do-while).
   a) What are loops used for?
   b) Write an example for each of them.

3. What is the difference between pre-test and post-test loops? When are they used?

4. Write down an if-elseif-else condition and explain how the individual parts work.

5. “Bugfixing”: The following code has several errors and minor flaws. Can you spot and fix all of them?

```python
def example():
    mid = [0 To 2]
    counter == 0
    while counter < 10
        rhinoscriptsyntax.AddCircle(mid,3)
    example()
```
I. Seventh Act: Make User Interaction Easier

[in which we supply parameters using the User Interface]

Graphical User Interface

Instead of writing `GenNStairs(10)` in Program 28, we want to present a user interface where parameters can be entered. In order to create a Graphical User Interface (GUI) you may rely on a UI creation tool like SharpDevelop (Version 4.4), which uses the Microsoft Windows Forms.¹ ² SharpDevelop is an integrated development environment that also supports Python. The workaround to create your own GUI is as follows:

- Open SharpDevelop (after you have installed it)
- Click File ... new ... File
- Select “Python” from the categories area (left) and choose “Form” from templates (right)
- Press create button
- At the bottom you’ll see that the “source” view is activated; choose “design” instead
- Select Tools on the left side and choose Windows Forms (see Figure 8)
- Now you can use all items under Windows Forms (e.g. a button); simply use drag and drop
- Properties of each element can easily be changed at any time (see right in Figure 8)
- Finally, save the file as “.py”-file

Figure 7: SharpDevelop 4.4; Left: items of Windows Form; Middle: design field; Right: properties.

¹ http://www.icsharpcode.net/opensource/sd/Default.aspx
² https://discourse.mcneel.com/t/can-winforms-be-used-with-python-to-make-this/17167/9
Look at the first lines of the new “.py” file (in SharpDevelop change to source view or compare Program 30). As you can see, the new file refers to certain modules (.NET assemblies). This includes the System module (line 1) and the Microsoft Windows Forms module (line 2). In line 3 and 4 you import all elements that are therein available. Finally, in line 5 you create your own class. A class describes a program code template (a blueprint) for creating objects (see more in the appendix K.5. Some more about Objects (VBA) on page 79). It describes properties and methods (behavior) of objects. In our case, we initialize our components (our previously inserted button) and define some properties, like its position (line 11).

### Program 30: Import Windows Forms

<table>
<thead>
<tr>
<th>Line</th>
<th>Code</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>import System.Drawing</td>
<td>import module Windows Forms</td>
</tr>
<tr>
<td>2</td>
<td>import System.Windows.Forms</td>
<td>import all elements</td>
</tr>
<tr>
<td>3</td>
<td>from System.Drawing import *</td>
<td>create your own class</td>
</tr>
<tr>
<td>4</td>
<td>from System.Windows.Forms import *</td>
<td>“self” refers to the current instance</td>
</tr>
<tr>
<td>5</td>
<td>class MainForm(Form):</td>
<td>initialize your components</td>
</tr>
<tr>
<td>6</td>
<td>def <strong>init</strong>(self):</td>
<td></td>
</tr>
<tr>
<td>7</td>
<td>self.InitializeComponent()</td>
<td></td>
</tr>
<tr>
<td>8</td>
<td>def InitializeComponent(self):</td>
<td></td>
</tr>
<tr>
<td>9</td>
<td>self._button1 = System.Windows.Forms.Button()</td>
<td>configure the element button1</td>
</tr>
<tr>
<td>10</td>
<td>self.SuspendLayout()</td>
<td></td>
</tr>
<tr>
<td>11</td>
<td>self._button1.Location = System.Drawing.Point(136, 133)</td>
<td></td>
</tr>
</tbody>
</table>

### VBA for AutoCAD: Form

Creating a user interface involves creating a new Form, using VBA's Form editor. The Form editor is within the VBA editor, so you can simply insert a UserForm: in the project Structure (ACADProject) use right click and choose Insert/UserForm.

![Figure 8: Form, Toolbox and Properties.](image)

What you see should be similar to the parts depicted in Figure 8 – a Form in the middle of the screen, a Toolbox nearby and a Property editor on the lower-left part of the screen.
We will now build up a form using three components: Labels, TextBoxes and Buttons. Open SharpDevelop click New and select Form template from category Python. Rename the class to StepUserInterface: choose “source” view and change class Form1(Form) to class StepUserInterface(Form). Now, change the “source” view to the “design” view. On the left side open Windows Forms in the Tools bar. Hover over A Label, and drag and drop it to the form (you can also click the symbol then change to the Form and click again). Do the same with ab| TextBox and the ab button.

Your form should contain three parts: a Label, a TextBox and a Button. Click on the Form (anywhere in the gray area will do) and look at the property editor (on the right). As example you can change the title of the form window by changing the text under the tab Appearance (e.g. “Enter Parameters”). Once finished, go click on the Label and set its Name under the tab Design to NumberOfSteps (again in the property editor). Set the Text (tab Appearance) of the Label to “Number of steps”. Click on the TextBox. Set its Name to Steps. Click on the Button and set its Text under the tab Appearance to OK. The Form should look similar to Figure 9:

![Figure 9: Our first UserForm](image)

Then double-click the Button, this should bring up the Editor (“source” view) with the command def Button1Click(). Note that you can return anytime to the form by clicking the “design” view.

Button1Click() is an event handler (see more in the appendix K.5. Some more about Objects (VBA) on page 79). It is being called whenever the user clicks on the OK Button. Inside Button1Click() come all commands you want to have executed. For example, we might write:

```python
def Button1Click(self, sender, e):
    self.Close() # remember, “self” refers to the current instance; this just closes the Form on click
```

Now, we save the new project (e.g. as DrawStepsGUI.py). You may be asked to save the Resource Files as well (DrawStepsGUI.resx). Switch to the PythonEditor in Rhino. Open the project in which you want to use the new GUI (in our case this is Program 28). In here we (e.g. at the end of the staircase program) have to import the new GUI File in order to use it (see line 1 in Program 31).
Program 31: Use GUI in your project

1 import DrawStepsGUI
2 if __name__ == "__main__":
3     form = DrawStepsGUI.StepUserInterface()
4     form.ShowDialog()
5     numSteps = int(form._Steps.Text)
6     GenNStairs(numSteps)

Line 2 is an if-condition, which is true as soon as the play button is pressed (as soon as the program is started). In the next line we initialize a new variable with the class StepUserInterface in DrawStepsGUI. Finally, in line 4 the command ShowDialog of the Form StepUserInterface is called. When pressing the green play button from the Rhino Python Editor the new GUI will appear. Once you press OK, the form window will hide itself (remember self.close() from before), and execution will finish. This brings us back to line 5 where we read whatever the user has inserted into the TextBox "_Steps". Since this is a string, we convert the value to an integer. Finally, we call the command from Program 28 (line 6)

Forms are Objects. They have different variables and Functions for working with the window you see. Try typing “DrawStepsGUI.StepUserInterface.” inside the Rhino Python Editor (handler). This should bring up the list of things available for calling.

VBA for AutoCAD: Form StepUserInterface

Execute the form editor by selecting it in the project view, then pressing the play button. Once you press OK, the form window will hide itself, and execution will finish.

Private Sub CommandButton1_Click()
    Hide
End Sub

Since Forms are Objects you are “inside” the object as soon as you are in a handler. Therefore, you can either use StepUserInterface.Hide or just Hide. Furthermore, each control you add (in our example: the Label, the TextBox and the Button) is available as Object inside the Form, accessible for example via StepUserInterface.Steps.

I.1. Useful Commands for Converting and Checking

Remember that we had to convert the insert of TextBox to an integer. But what if the user types "blah"? This cannot be converted into an Integer. Consequently, we have to check the input for correctness. The following program illustrates some string functions that come handy. They may be useful when fields of a GUI should only allow certain inputs:
Program 32: Strings

```python
def checkInput():
    s = "123,3"
    if s.isnumeric():
        s = int(s)
    else:
        s = s.replace("", ",").replace(".", ",")
    if s.count(".") == 1:
        onlyChars = s.replace("", ",")
        if onlyChars.isnumeric():
            s = float(s)
        else:
            print "try again!"
    checkInput()
```

The function isnumeric() on line 3 returns True if the passed string contains only numeric characters. In this case, the input is a whole number and we can immediately convert the string into an int (line 4).

**Hint!** Programming means to use the English notation for numbers (e.g. 0.3 and not 0,3). This is important when dealing with floating-point numbers.

In our command we want to consider country-specific writing styles. I.e. the separation mark between the integer and the decimal part of a floating-point number can be either a point or a comma. Consequently, we, at first, use the function replace() in order to change any comma to a point (see line 6). Thereafter we search for exactly one point in (s), which is an indication for a floating-point number. Since the string can nevertheless contain none numeric characters we eliminate the point and check if the remaining string (onlyChars) isnumeric() (line 9). If yes, the original string is a floating-point number and (s) can be converted into a float (line 10). In all other cases (s) is a string.

VBA for AutoCAD: Strings

In contrast to Python (Program 32), the VBA function IsNumeric considers floating-point numbers as well. Moreover, VBA also considers different country-specific writing styles (comma and point). We will therefore use the result of the function IsNumeric on line 4 together with an If-condition to convert a string to another data type.

```vba
Sub checkInput()
    s = "123,3"
    If IsNumeric(s) Then
        check if string contains only numbers
```
If InStr(s,",”) <> 0 Or InStr(s,".")) Then
  Dim d as Double
  d = CDbl(s)
Else
  Dim i as Integer
  i = CInt(s)
End If
End If
End Sub

- After knowing that the string represents a number, we check for the existence of a decimal point. This lets us know whether it is a floating-point number or a whole number. As different countries write the decimal point in different ways ("." for the U.S., ",” in Austria), we have to check both cases using the logical Or.
- The conversion from string to a different type must be triggered manually by using CInt ("convert to Integer") or CDbl ("convert to Double"). Additionally, there is the function CBool (which is used in due course) that converts from a string to Boolean.

The important point why we do this is to now get the number of steps (a string) from the previously defined form. This must be checked e.g. if it is empty, if it is a number, then converted to integer. And then, we may finally call the stair algorithm in order to do useful work.

We now turn back to our staircase program where we have added our GUI (see Program 28 and Program 31). After we call the Form, we add the checkInput program (see Program 32):

- In order to obtain the value of the TextBox, we use “form._Steps.Text”.
- If the user has not typed anything into the TextBox, we ask him to enter something.
- If we find (after many checks) that the value is an integer, we call the steps program, passing the converted integer value as number of steps.

Program 33: Handler that calls the steps program

```python
import DrawStepsGUI
if __name__ == “__main__”:
    form = DrawStepsGUI.StepUserInterface()
    form.ShowDialog()
    if form.Button1Click:
        s = form._Steps.Text
        if len(s) == 0:
            rs.MessageBox(“Enter a value”) if True then show message
        else:
            if not(s.isnumeric() or
                isFloat(s)):
                rs.MessageBox(“Enter num”) if True then show message
            else:
```
You might recognize that no function called “isFloat” exists (line 10). In other words, this is a new function (see Program 34). Basically, the new function replaces any comma with a point (regardless how many there are). In case there is exactly one point in the string it might be a floating-point number (see Program 34 line 3). Next, we remove the point and look if it is now a number (line 4 and 5). This is the final indication that (value) is a floating-point number.

**Program 34:** Function isFloat

|   | def isFloat(value):
|---|---
| 1 | value = value.replace(“,”,”.”) replace comma with point, even if there is none
| 2 | if value.count(“.”) == 1: if there is exactly one point, it might be a number
| 3 | onlyChars = value.replace(“.”,”.”) remove point
| 4 | if onlyChars.isnumeric(): check if it’s now a number
| 5 | return True

**Hint!** The order of your functions in the program is important. I.e. each function you call has to be defined previously in the code.

**VBA for AutoCAD:** Handler that calls the steps program

|   | Private Sub CommandButton1_Click
|---|---
| 1 | Dim s As String
| 2 | s = Steps.Value
| 3 | If Len(s) = 0 Then
| 4 | MsgBox(“Enter a value for steps”) Exit Sub
| 5 | End If
| 6 | If IsNumeric(s) Then
| 7 | If InStr(s,”.”) <> 0 Or InStr(s,”,”) Then MsgBox(“Enter an Integer.”)
| 8 | Else
| 9 | Dim i As Integer
|10 | i = CInt(s)
|11 | GenNSteps i, 18, 32, 0, 0
|12 | Hide
|13 | End If

|   | replace comma with point then convert to integer start program
Else
    MsgBox("Please enter a number.")
End If
End Sub

I.2. Summing up this chapter

Filling a program with parameters in a graphical way has lead us to dive into user interfaces, or (as called in Windows) Forms. A Form is an object onto which you can draw controls (e.g. TextBoxes, Labels, Buttons). These controls are available by prepending the form’s name (a TextBox “Steps” of a Form “StepUserInterface” would be, after calling the Dialog, accessible via “._Steps”). We have also seen handlers in the form of a click handler for the “OK” Button. A handler is a code inside the form that usually does some error-checking on the form’s controls and then goes on to call some program. There are many handlers available (but beyond scope of this lecture), for example for handling keypresses, selection of a list etc. We encourage the reader to look inside these when the basic knowledge has settled.

I.3. Questions

1. Write a GUI with a TextBox, a Label, a Button and a fourth element. Check for valid inputs, e.g. max characters of the TextBox, no number in the TextBox or the like.
2. Search for an alternative possibility to check for numbers (hint: error checking).
J. Eight Act: Interact with Grasshopper

[in which we want to open the communication between Grasshopper and Python]

The prerequisite for communication between Grasshopper and Python programs is to install the open source component GhPython. GhPython is a scripting component which allows to use the rhinoscriptsyntax (which is exactly what we need). How to install:

- Download the component e.g. from food4rhino.¹
- Save the file (ghpython2.gha) in the Component Folder of Grasshopper: in Grasshopper, choose File/Special Folder/Component Folder.
- Right click on the file, open properties and make sure that it is not blocked.
- Close Grasshopper and restart Rhino.

Now, you can use GhPython. You’ll find the component under Math/Script (see Program 11).

Figure 10: Left: GHPython in Grasshopper; Right: Insert a slider and connect it to Steps parameter.

J.1. GHPython component

Similar to other Grasshopper components you can manipulate the two input parameters (x) and (y) (you can rename, add or remove them). On the other side there is again an output parameter (out) for execution information (output and error streams) and one for a result parameter (a). The number of output parameters can be changed as well. For the moment we will remove the y-input and rename the x-input to Steps (right click on x and change name at the top). Add a slider for Steps (integer between 1 and 20) and connect it with the input parameter Steps (see Figure 10 right).

Now we want to call our staircase program inside the component. Double click on the component will open the script window. In there we have to import our staircase program. How to do this? First we import the sys module (see Program 35 line 1). We need to do this in order to add a sys-folder which contains our staircase program (see line 2). Finally, on line 4 we import the staircase.py program (compare Program 28).

¹ http://www.food4rhino.com/app/ghpython (30.03.2018)
**Program 35: GHPython call .py program**

```python
1 import sys
2 ghFile = str('D:\..\41 Tests')
3 sys.path.append(ghFile)
4 import staircase
5 reload(staircase)
6 a = C08StaircaseGH.StepByStep(Steps)
```

In the staircase.py file we have to comment out the call of the command on the last line and to return the polyline (in order to “get it into our hands”):

```python
return rs.AddPolyline(points)
#GenNStairs(10)
```

Finally, we have to call the function in the GHPython component and equate the result to the output parameter (a) (see Program 35 line 6). Only if we hand over the result to (a) Rhino draws the final polyline.

But, what if we want to draw the polyline directly in Grasshopper? In this case we return a list of point-coordinates (instead of a polyline). In Grasshopper we then turn this list into a list of points, since polyline asks for vertices. You just have to change the last line of our .py-program:

**Program 36: GHPython call .py program**

```python
1 import rhinoscriptsyntax as rs
2 def SingleStep(x,y,z,StepDepth,StepHeight,points):
3    y = y + StepHeight
4    point = [x,y,z]
5    points.append(point)
6    x = x + StepDepth
7    point = [x,y,z]
8    points.append(point)
9    return (x,y,points)
10 def StepByStep(NumberOfSteps):
11    StepDepth = 32
12    StepHeight = 18
13    x = 0
14    y = 0
15    z = 0
16    point = [x,y,z]
17    points = []
```
In Grasshopper, connect the output (the list of point-coordinates) to a point component. This will turn the points-coordinates into a list of points. Finally, connect the new list of points with a polyline component (see Figure 11):

![Figure 11: Draw polyline with Grasshopper component.](image)

**J.2. Questions**

1. Change the staircase program and the GHPython component so that you can insert the StepHeight and StepDepth directly in Grasshopper (similar to Steps).
K. Epilog: Circles in a Polygon

[in which we want to close with a final program]

First we start with a description of the new program: We want to draw (n) non-overlapping circles within one or more predefined closed polylines. For a better distinction, these polylines are on a specific layer (let’s name the layer PlanningArea; red lines in Figure 12). In addition, the circles have to avoid the inside of closed polylines on another layer (let’s call this layer ExistingBuildings; yellow lines in Figure 12). A possible outcome is given in Figure 12:

\[\text{Figure 12: The Circle program.}\]

K.1. Select curve on layer

Since we want to draw inside predefined polylines on a layer named PlanningArea, we have to write a function that gives back all polylines on a given layer.

Program 37: Get elements on certain layer

<table>
<thead>
<tr>
<th>Line</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>import Rhino</td>
</tr>
<tr>
<td>2</td>
<td>def ObjOnLayer(layername):</td>
</tr>
<tr>
<td>3</td>
<td>rhobjs = Rhino.RhinoDoc. ActiveDoc.Objects. FindByLayer(layername)</td>
</tr>
<tr>
<td>4</td>
<td>if not rhobjs:</td>
</tr>
</tbody>
</table>

import module Rhino

use function FindByLayer() of module Rhino (which does what you need): all objects on layer are stored in a variable (rhobjs)

check if (rhobjs) is empty
If you look at line 9, you may recognize that all Rhino objects are added to the list, no matter if it is a (closed) polyline or not. This may be improved by yourself. (Homework)

In the next step we want to get the bounding box of all elements on layer "PlanningArea":

In our main program, we call the command GetBoundingBox() and hand over the two returned corner points to a command called DrawCircles():

Now we want to draw n-circles of radius (r) within the bounding box:
**Program 40:** draw Circles within bounding box

1. import random as rnd
2. def GetRndPoint(minPt, maxPt):
   3.   x = rnd.uniform(minPt[0], maxPt[0])  # get random number between min x-val and max x-val
   4.   y = rnd.uniform(minPt[1], maxPt[1])  # get random number between min y-val and max y-val
   5.   pt = [x, y, 0]
   6.   return pt  # return the point within bounding box
3. def DrawCircles(minPt, maxPt):
   4.   for i in range(0, n):  # repeat n-times (i is a counter)
   5.     pt = GetRndPoint(minPt, maxPt)  # get random point within bounding box
   6.     rs.AddCircle(pt, r)  # draw circle

Program 40 results in overlapping circles within a bounding-box. However, we want none-overlapping circles! How can we achieve this? We can calculate the distance between a (randomly) generated midpoint to every other midpoint of already existing circles (which means we have to store all midpoints of previously drawn circles in a list). We only draw a circle (and add it to the list of midpoints) if no distance is smaller than two times the radius (r). But this opens up a new problem. What if we want to draw n-circles, but there is only space for less (e.g. n-1)? You are right when you say that we simply need a second abort criterion (e.g. another counter inside the for-loop):

**Program 41:** Check distance between new midpoint and existing ones

1. import rhinoscriptsyntax as rs
2. import math
3. def getDist(x1, y1, x2, y2):
   4.   dist = math.hypot((x1-x2), (y1-y2))  # Pythagoras: calculate hypotenuse
   5.   return dist
6. def CheckOverlapping(pt, midPts):
   7.   isOverlapping = False
   8.   if len(midPts) > 0:  # check if at least one midpoint exists in list
   9.     for midPt in midPts:
   10.    dist = getDist(pt[0], pt[1], midPt[0], midPt[1])  # get distance between generated point (pt) and current midpoint in list
   11.   if dist < (2 * r):  # check if distance is smaller than two times the radius

    If we want to draw n-circles, but there is only space for less (e.g. n-1), we can use the `CheckOverlapping` function to check if there is enough space for the next circle.
Program 41: Check distance between new midpoint and existing ones

12     isOverlapping = True if yes, the circle of the generated midpoint overlaps an existing circle
13  return isOverlapping return the result (true or false for overlapping)
14 def DrawCircles(minPt,maxPt):
15  midPts = [] initialize an empty list to store all midpoints
16  for i in range(0, n): loop n-times (for n circles)
17    j = 0 initialize a counter j with 0
18    while j < m: loop m-times (for m tries to draw a single circle)
19      j = j + 1 don’t forget to increase j!
20      pt=GetRndPoint(minPt,maxPt) get a random (mid)point
21      if CheckOverlapping(pt, midPts) == False: check if the circle with (mid)point overlaps with an existing circle
22        rs.AddCircle(pt,r) if not, then draw circle
23        midPts.append(pt) append new midpoint to list
24        j = m we don’t need a further try, so equate counter to max tries (m)

Still we have a distribution of circle within the bounding box, but not within the given polylines on layer PlanningArea. So we have to insert another abort criterion (before line 22 of Program 41):

Program 42: check if midpoint is in PlanningArea

1  import rhinoscriptsyntax as rs
2  def CheckInArea(pt,layerName):
3    result = False at the very beginning we say that the point is outside the PlanningArea
4    objs = ObjOnLayer(layerName) we already know this (see Program 37 line 12)
5    for obj in objs: we check for every object on layer PlanningArea
6      curve = obj.Geometry convert obj into curve
7      if rs.PointInPlanarClosedCurve (pt,curve) == True: check if (pt) is within an object on layer PlanningArea
8        result = True if yes, result is true
9        return result hand over the result to caller
10  def DrawCircles(minPt,maxPt):
11    ... see line 15-20 of Program 41
12    if CheckOverlapping(pt, midPts) == False:
13      if CheckInArea(pt, ”PlanningArea”) == True: call function CheckInArea
**Program 42:** check if midpoint is in PlanningArea

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>14</td>
<td>rs.AddCircle(pt,r)</td>
</tr>
<tr>
<td>15</td>
<td>midPts.append(pt)</td>
</tr>
<tr>
<td>16</td>
<td>j = m</td>
</tr>
</tbody>
</table>

And what about the addition that the circles have to avoid the inside of closed polylines on another layer (called ExistingBuildings). Now you will recognize the advantage of programming with commands (procedural). You just have to insert another query after line 12 of *Program 42*. This time we ask if the point is not inside an object on the layer ExistingBuildings:

```python
1   def DrawCircles(minPt,maxPt):
2      ...
3     if CheckOverlapping(pt,midPts) == False:
4        if CheckInArea(pt,"PlanningArea") == True:
5           if CheckInArea(pt,"ExistingBuildings") == True:
6              rs.AddCircle(pt,r)
7              midPts.append(pt)
8              j = m
```

Now you might say: we are finished. But have a look at *Figure 13*. You see that some circles are overlapping the border lines.

*Figure 13: The Circle program so far.*
So let’s insert a last check for intersection with border lines of the planning area and the existing buildings:

**Program 43: check for intersection**

```python
1 import rhinoscriptsyntax as rs
2 def CheckIntersection(tempCircle, layerName):
3     objs = ObjOnLayer(layerName)
4     for obj in objs:
5         curve = obj.Geometry convert circle into curve
6         intersects = rs.CurveCurveIntersection (curve,tempCircle) we use a function of rhinoscriptsyntax to check intersection
7         if not intersects == None: “not none” means that both objects intersect
8             return True therefore return True
9 def DrawCircles(minPt,maxPt):
10    ...
11    tempCircle = rs.AddCircle(pt,r) store circle in variable
12    if not CheckIntersection(tempCircle, “PlanningArea”) == True and not CheckIntersection(tempCircle, “ExistingBuildings”) == True: checks intersection with objects on layer PlanningArea and on layer ExistingBuildings
13        midPts.append(pt) if no intersection exists, delete circle
14        j = m we don’t need a further try, so equate counter to max tries (m)
15    else: in all other cases
16        Rhino.RhinoDoc.ActiveDoc.Objects. Delete(tempCircle, True) delete circle (because it intersects a border line)
```

You can now call the file within a GHPython component in Grasshopper and add sliders for the three input parameters (homework):

- \( r = 1 \) (radius of circles)
- \( n = 30 \) (number of circles in best case, if all tries to set a circle are successful)
- \( m = 30 \) (number of tries to set a single circle; exclusion criteria are: overlapping with other circles, placement outside objects on layer PlanningArea, placement inside objects on layer ExistingBuildings and intersection with border lines)
K.2. Questions

1. Think about what happens if no object is on the layer PlanningArea and ExistingBuildings. At which line of code would you insert such a query?
2. Test the code and look if there are other cases that produce an error.
Appendix

Some code snippets that might be interesting:

Program 44: add layer to project

```python
1 import Rhino
2 def AddLayer(layerName, col):
3    layerIndex = Rhino.RhinoDoc.ActiveDoc.
4        Layers.Find(layerName, True)
5    if layerIndex>=0:
7    layerIndex = Rhino.RhinoDoc.ActiveDoc.
8        Layers. Add(layerName, col)
9    if layerIndex<0:
10       return Rhino.Commands.Result.Failure
11       return Rhino.Commands.Result.Success
```

Program 45: delete objects on a layer

```python
1 import scriptcontext as rc
2 def DeleteObjectsOnLayer(layerName):
3    rhobjs = Rhino.RhinoDoc.ActiveDoc.
4        Objects.FindByLayer(layerName)
5    if not rhobjs:
7    else:
8        for obj in rhobjs:
9            Rhino.RhinoDoc.ActiveDoc.
10           Objects.Delete(obj, True)
11        rc.doc.Views.Redraw()
12        return Rhino.Commands.Result.Success
13 DeleteObjectsOnLayer("layerName")
```

layer/ (31.03.2018)
K.3. Some more about Arrays (VBA)

**VBA for AutoCAD:** Change the size of an array

In VBA, the declaration of an array (a list with entries of the same data type) is similar to any other variable of simple data type (e.g. integer, doubles or booleans). The only difference are the brackets after the name of the variable. If one knows the number of entries beforehand, the first and last index are given in the brackets, separated by the connective "to":

```vbnet
Dim point(0 to 2) As Double
```

The number of entries can be enlarged at a later stage (if one does not know the exact number of necessary entries beforehand). In this case, at first, an empty array has to be declared. The number of fields in an array can then be changed by **ReDim Preserve**. The term **preserve** means that already saved values remains after enlargement:

1. Dim field() As String declaration of an empty array
2. ReDim Preserve field(1 To 3) As String enlarge the array to 3 entries
3. field(1) = “first value” initialize first field
4. field(2) = “second value”
5. field(3) = “third value”
6. Redim Preserve field(1 To 10) As String enlarge the array to 10 entries
7. MsgBox(field(1)) first value is still there
8. Redim field(1 To 10) As String
9. MsgBox(field(1)) field(1) gives “”

**Hint!** Don't forget to write preserve if you don't want to loose previous saved values. To mistype the name of the array, while using ReDim, means to create a new variable. In this case, the "old" array remains as it is.

K.4. Some more about Sub, Function and Parameters (VBA)

**VBA for AutoCAD:** Peculiarities with parameters

When trying the new appendTo Sub, we notice some peculiarities in how VBA handles **Sub** and **Function** with more than one parameter, as sometimes you need to give brackets, sometimes not. We here give the rules on “when to use brackets when calling Subs and Functions”, plus some examples:

**Rules for brackets in VBA** (keep under your pillow)

- Rule 1: Calling a Function without using its result => consider as Sub.
- Rule 2: Calling a Sub or Function with one parameter => use brackets.
- Rule 3: Calling a Sub with multiple parameters => do not use brackets.
- Rule 4: Calling a Function with multiple parameters => use brackets.
...  
Dim result As Double  
OneParameterSub a  
TwoParameterSub a, b  
result = OneParameterFunction(a)  
OneParameterFunction a  
result = TwoParameterFunction(a, b)  
TwoParameterFunction a, b  
‘and in the case of our new Sub:  
Dim points() As Double  
appendTo points 10.2  
...

K.5. Some more about Objects (VBA)

VBA for AutoCAD: AutoCAD’s drawing API

An Application Programmer’s Interface (API) is a set of Functions or Subs are exposed by an application so that you can issue the same commands that normally come from interacting with its user interface (see Figure 14, right). In AutoCAD’s case, the API is exposed by the way of the ThisDrawing Object you see in the project structure.

VBA is an object oriented programming language and everything in VBA is actually an object. But what does this mean? An object is a collection of variables, Commands and Functions into a common package (“the Object”). In short, objects are container that hold together methods (procedures), attributes and events.

- Methods are blocks of code that take input and generate output, similar to commands and functions.
- Attributes are properties of an object (e.g. color).
- Events are messages sent by objects. They occur by changing the state (e.g. after a user action – if a user clicks the mouse). Another example for an event is: one should be informed if a file is saved in order to write the data into another file. This other file is consequently always as actual as the saved one.

By using the object’s name and appending a point, you get access to all contained entities. The small window you will see is also called IntelliSense, it can be very helpful in suggesting possible variables, Commands, Functions and their parameters without the programmer having to look at documentation.

Already ThisDrawing is an object (see Figure 14, left). If you type it into the code window, intelliSense offers all possible variables and commands you can use, e.g. ModelSpace. ModelSpace (as the help tool says) contains all graphical objects (entities) in model space. Some commands are:
• AddLightWeightPolyline (adds a polyline)
• AddLine (adds a line)
• AddCircle (adds a circle)
• AddBox (adds a 3D-box)
• AddSphere (adds a 3D-sphere)
• AddText (adds a text)

You’ll find more informations about objects in the Object Catalogue (view menu/object browser, or press F2 key; see Figure 14, right). It is an index over all objects that are known to VBA. Furthermore, there is still the F1 help which you might use in combination with selecting the word “AddLightWeightPolyline” – this brings up the help file on AddLightWeightPolyline and a more elaborate description with examples.

Figure 14: Left: Contents of ThisDrawing in VBA for AutoCAD. Right: Object Catalogue with AutoCAD API.

VBA for AutoCAD: Storing objects in variables

All drawing functions will hand you back the objects they have created. Take a look at the documentation for the specific drawing function in order to know what it will return (see Object Catalogue). By the way, objects may contain other objects, too.

If you want to store the object coming from a drawing function, you have to define a variable of the type that comes back, e.g. Dim sphere As AcadLWPolyline on line 2. Important: This variable cannot be set with the normal assignment. All variables that hold objects must be set using the Set keyword (see line 3).

Once you have the object in your variable, you can access its Functions, Subs and variables by appending a dot “.” to the variable’s name. See line 4 for an example of this.

```
1 Sub GettingHoldOfObjects()
2  Dim Staircase As AcadLWPolyline
3  Set Staircase = ThisDrawing.ModelSpace.AddLightWeightPolyline(points)   ' don’t forget “set”
4  MsgBox(Staircase.ObjectName)
5 End Sub
```
